The functions of the Golgi apparatus during oocyte maturation is still not well understood, although there is evidence that it is not just a spectator in this process. In somatic cells, the Golgi's primary function is to post-translationally modify, sort, pack, and release proteins and macromolecules for inclusion into other intercellular compartments, insertion into the cell membrane, or for exportation to the extracellular environment. When an inhibitor of membrane trafficking is used during in vitro oocyte maturation (brefeldin A), meiosis is arrested (Moreno et al., 2002). So, even though it is not yet known exactly how, the Golgi's involvement in membrane trafficking appears to be critical for meiotic resumption (Coticchio et al., 2015). Interestingly, a cis-Golgi matrix protein, GM130 is also involved in recruitment of microtubule enucleators such as γ -tubulin (Rivero et al., 2009). Based on this evidence and the fact that some species of oocytes do not have MTOCs, it has been suggested that the Golgi is also involved in spindle formation.

Cortical granules (GCs) are small secretory organelles that function to prevent polyspermy (entry of more than one sperm into the oocyte). They are not found in somatic cells but are present in all mammalian oocytes (Wessel and Wong, 2009). At the GV stage, the CGs are widely distributed throughout the ooplasm, but with the transition to MII stage, CGs aggregate just beneath the oolema (Coticchio et al., 2015). These organelles are vesicles containing cross-linking enzymes, proteases, glycosidases, and structural proteins. They are activated when the first sperm enters the oocyte triggering intracellular Ca^{2+} oscillations that then cause CGs to fuse with the oolema, and to extrude their contents. This exocytosis of CGs, alters the oolema, preventing entry of additional sperm. This cascade is known as the "cortical reaction" and the "block to polyspermy" and is the final act of cortical maturation.

Cortical Maturation

The oocyte cortex is a relatively undefined region that includes the oolema and the cytoplasm directly beneath. "The cortex functions as a boundary zone that gives the cell its shape, a region of selective exchanges and transductions, an active partner for the cytosolic

Fig. 3 Oocyte cytoplasmic maturation.

Fig. 4 Structural meiotic maturation. This set of images show the power of immunofluorescence and confocal microscopy. The confocal laser scanning microscope enables visualization of the inner workings of a cell. Here, we have used a mixture of antibodies and dyes labeled with fluorescent molecules to identify multiple structures within each oocyte at different stages of maturation. Female mice were treated with hormones to induce the growth of multiple antral follicles, a procedure similar to those used in clinical assisted reproduction for women. After 2 days of antral follicle growth, oocyte maturation is induced by treating the females with an LH-like hormone. The oocytes are then collected from the ovaries at specific times post-LH, times that are associated with the various stages of oocyte maturation: row A = 0 h GV; row B = 2 h GVBD; row C = 8 h MI; row D = 16 h MII; row E = 16 h meiotic check-point arrested at telophase-I. Column “Combined” is all of the markers over-layered and shown together, including the non-fluorescent view from differential interference contrast (DIC). Column “DIC-off” is the same as “Combined” but only showing the fluorescently labeled structures. The computer software is used to add the colors that we see as *blue* (DNA), *red* (actin), and *green* (tubulin and/or Src-family kinases, SFK). Columns “Microtubules”, “Actin”, and “DNA” are showing the images from single wavelengths, thus the individually labeled structures. We have chosen to show microtubules by identifying two different families of proteins. A and B are labeled with an antibody that identifies activated Src-family kinases. The SFKs are found closely associated with microtubules, so they can also be used to identify the MTOCS (Ac and Bc, *white arrows*), and also shows the polarized location of activated SFKs in the cytoplasm near to the cortex (gradient layer surrounding the oocyte in Bc, *red arrow*). Rows C, D, and E are oocytes labeled with a mixture of two antibodies to identify alpha and beta tubulin, thus only the meiotic spindles are visible (Bc *yellow arrow*, Cc, Dc, Ec). With the addition of DIC, it’s possible to see the dense aggregates of intracellular organelles (Ca, Da *arrows*). Cd and Dd *asterisks* = actin cap over the MI (Cd) and MII (Dd) spindles. Row E—an oocyte that failed to complete MI and was arrested at telophase-I. The confocal microscope demonstrates the cause of this meiotic failure; the chromosomes in Ed have been enlarged to show that the oocyte suffered a lost chromosomes (Ed *arrow*), trapped within the midbody of the telophase spindle, a condition that triggered a meiotic “check point arrest” (Gorbsky, 2015). If this oocyte had completed meiotic maturation with abnormal chromosome segregation, the resulting MII oocytes would have had either an extra or a missing chromosome, a serious and potentially fatal meiotic error called aneuploidy. Images were taken on a Zeiss LSM Pascal scanning confocal microscope. Each image is 10 μm thick. *White bars* show scale: A = 10 μm, C and D = 5 μm). Actin labeled with phalloidin; DNA labeled with Hoechst 33258; activated SFKs labeled with “clone28” antibody; tubulin labeled with anti-tubulin antibody.

cytoskeleton and organelles, and a preferred site for the localization of RNA and protein determinants. It has the properties of a viscoelastic gel and functions as a unit during many cell behaviors" (Sardet et al., 2002). The cortex includes the oolema and the nearby subcortical region including cytoskeleton and cytoplasmic components that are polarized to this region adjacent to the oolema. During oocyte maturation, the cortex undergoes changes that are critical for the completion of meiosis and to enable fertilization. This process includes the movement of organelles and cytoskeleton as mentioned earlier plus changes in the oolema and regionally localized proteins.

Using confocal microscopy, McGinnis and Albertini demonstrated a polarized activation of kinases, including Src- and MAPK-family proteins associated with cell cycle and fertilization (McGinnis and Albertini, 2010). As the oocyte matures, there is a dramatic increase in tyrosine phosphoproteins and Src-family kinases associate with the oolema, while serine/threonine and MAPK-family kinases are activated in the subcortical layer (McGinnis and Albertini, 2010; McGinnis et al., 2011). This reorganization and activation of proteins to the cortex is, like other movements during maturation, preparing the oocyte for sperm entry and a rapid response to fertilization.

Movement of the metaphase spindle to the cortex induces the formation of a thick cortical actin layer immediately overlaying the spindle, often called the "actin cap" (Fig. 4Cd and 4Dd, *asterisk*). This dramatic polarization is accompanied by changes in cortical tension and reorganization of proteins associated with actin dynamics, such as myosin-II and the ezrin/radixin/moesin proteins (Larson et al., 2010). The formation of this dense actin layer is associated with changes in the oolema creating a "microvilli-free zone" directly over the MII spindle. Microvilli are small protrusions of the cell membrane that cover most of the oocyte surface. Sperm normally only enter the oocyte in regions where they contact microvilli, therefore the microvilli-free zone reduces the chance for sperm to enter the egg too close to the MII spindle where sperm are susceptible to extrusion with the polar body (Luo et al., 2009). Cortical maturation is another critical step in oocyte maturation, setting the stage for another meiotic arrest while the oocyte waits for fertilization.

Oocyte maturation is a complex event, carefully orchestrated to match structural elements and molecular signaling cascades. Once maturation is complete, oocyte meiosis arrests in metaphase-II and awaits sperm entry and fertilization. This must occur quickly because mammalian oocytes only maintain optimal fertilizing capacity for a limited time. In the mouse, this window of opportunity is the period between 14 and 18 h after the LH-surge. In humans, the optimum fertilization window is presumed to range from 24 to 36 h post-LH, but the specifics are not well known due to the limitations of this type of research on human oocytes. It is known however, that mammalian oocytes can suffer from postovulatory aging which includes a slow migration of the spindle away from the cortex and an increased susceptibility to abnormal egg activation, apoptosis, and aneuploidy (McGinnis et al., 2014).

Summary

Oocyte structural maturation is a complex event that must occur rapidly and in synchrony involving dramatic movements of intracellular components and polarizing shifts, all with a purpose of preparing the oocyte for fertilization and to support the development of a healthy embryo.

Chromatin Modifications During Mammalian Oocyte Growth and Meiotic Maturation

Introduction

In mammalian species the process of oocyte growth and maturation ensues from a pool of primordial follicles that become activated shortly after birth. Throughout postnatal development, oocytes are maintained in a protracted meiotic arrest with an intact nucleus at the diplotene stage. Oocyte growth takes place within the ovarian follicle and is regulated by an intimate bidirectional communication with surrounding granulosa cells. The paracrine signals between germ cells and granulosa cells that regulate this process are not clear at present. However, three oocyte intrinsic developmental programs (nuclear maturation, cytoplasmic maturation and epigenetic maturation) are essential for oocyte growth and acquisition of developmental potential. Mouse oocytes first acquire the capacity for nuclear maturation approximately on day 14 of postnatal development following synthesis and accumulation of cell cycle regulatory molecules required to resume and complete the first meiotic division (Fig. 1). Cytoplasmic maturation is acquired during the final stages of oocyte growth and involves a series of metabolic changes that prepare the oocyte for fertilization, pronuclear formation and the first cleavage division before transcriptional activation of the embryonic genome (Fig. 1). Epigenetic maturation involves a series of chromatin modifications that affect the patterns of gene expression without exerting any changes at the level of the DNA sequence. These changes can occur on a genome-wide basis, on specific chromosomal domains such as centromeres and telomeres or may affect chromatin composition and structure at the single gene level thus may directly impact the regulation of global transcription and/or specific gene expression patterns (De La Fuente, 2006).

Epigenetic modifications may induce stable and heritable changes in gene expression through DNA methylation, the induction of histone post-translational modifications such as histone methylation, acetylation, phosphorylation and poly(ADP) ribosylation or the incorporation of histone variants at specific chromosomal domains such as the specialized centromeric histone H3 variant CENP-A or the replication independent H3.3 variant. Epigenetic modifications are required for the control of transcription, nuclear

Fig. 1 Epigenetic modifications during mammalian oocyte growth. Functional differentiation of chromatin structure is essential to confer the oocyte with meiotic and developmental potential. During postnasal oocyte growth nuclear maturation, cytoplasmic maturation and epigenetic maturation determine chromosome stability and establishment of maternal imprinting.

architecture, establishment of DNA methylation patterns and maintenance of chromosome stability during meiosis (De La Fuente, 2006).

The mammalian oocyte nucleus or germinal vesicle (GV) is subject to dynamic chromatin modifications at several developmental transitions in preparation for meiosis. At the local level, targeted chromatin modifications at regulatory DNA sequences of specific loci establish oocyte-specific DNA methylation marks, a maternal genomic imprint. Superimposed on these local chromatin changes lays an important nontargeted strategy for the control of global transcription and large-scale chromatin remodeling (De La Fuente, 2006). Large-scale chromatin structure is regulated by multiple and hierarchical global chromatin modifications induced by chromatin remodeling proteins and histone post-translational modifications required for heterochromatin formation and the epigenetic control of centromere function (De La Fuente et al., 2012). Notably, specialized mechanisms are set in place for the control of large-scale chromatin remodeling in the female germ line in order to cope with the unique requirements of meiotic chromosomes (De La Fuente, 2006, 2014; Kimmins and Sassone-Corsi, 2005; Revenkova et al., 2004; Ivanovska and Orr-Weaver, 2006).

The mechanisms regulating the 'meiotic histone code' are only beginning to be unraveled through the generation of transgenic mouse models and the use of genome-wide transcriptome and DNA methylome analyses. These are powerful strategies that will accelerate our understanding of how the meiotic histone code, or changes in large-scale chromatin structure regulate genome function during oogenesis and the maternal inheritance of epigenetic states to the early embryo. This will be critical to gain a mechanistic understanding of the epigenetic origins of chromosome instability, genomic reprogramming and the control of gene expression during the mammalian oocyte to embryo transition.

Establishment of DNA Methylation During Postnatal Oocyte Growth

Establishment of DNA methylation during oogenesis occurs on a locus-by-locus basis and both histone modifications and transcription at regulatory sequences called imprinted control regions (ICRs) or differentially methylated regions (DMRs) located within the 5' flanking regions of imprinted genes dictate the placing and timing of methylation marks. Genomic imprinting results in the establishment of a gamete-specific mark that is strictly required for normal embryonic development, placental differentiation and fetal growth (Hackett and Surani, 2013; Weaver and Bartolomei, 2014). During early postnatal development, maternal-specific DNA methylation patterns begin to be re-established in the growing oocytes within primary follicles. Beginning with day 5 of postnatal development and coincident with the transition from primary to secondary follicles, maternal methylation imprints are established, progressively at different genes, a process that is mostly completed by the germinal vesicle stage before global transcriptional repression takes place in fully-grown preovulatory oocytes (Lucifero et al., 2004; Smallwood et al., 2011).

Establishment of methylation marks at different genes depends on oocyte growth. De novo methylation occurs around the time when the oocyte reaches 50 μ m in diameter and different genes acquire their final methylation status in different oocyte size populations. The time of establishment of DNA methylation marks at specific loci during oogenesis has been described (Lucifero et al., 2004; Smallwood et al., 2011). However, less is known about the primary mechanisms regulating the establishment of de novo DNA methylation at specific imprinted genes during oogenesis. Elegant studies provided the first evidence that the DNA methyltransferase enzyme DNMT3A exhibits de novo methylation activity and that together with its catalytically inactive regulatory cofactor DNMT3L regulate the establishment of DNA methylation at several imprinted loci in mouse oocytes (Kaneda et al., 2004; Hata et al., 2002; Bourc'his et al., 2001). Additional studies indicated that the histone H3 lysine 4 demethylase (KDM1B) is also required for DNA methylation of several but not all maternally imprinted genes during oocyte growth (Ciccone et al., 2009). The precise role of KDM1B in this process remains to be determined. However, it has been suggested that KDM1B may induce demethylation of histone H3 at lysine 4 (H3K4), potentially inducing an open chromatin configuration to recruit the de novo DNA methylation machinery to specific imprinted loci (Ciccone et al., 2009). A different study provided compelling evidence that the KRAB/zinc finger protein Zfp57 is required for methylation of the *Snrpn* locus through a potential interaction with the chromatin binding protein KAP1 (also known as TRIM28), which is known to establish an interaction with the histone methyltransferase SETDB1 and DNMT3A (Li et al., 2008; Messerschmidt et al., 2012; Quenneville et al., 2011).

One of the most intriguing recent discoveries on the mechanisms of oocyte de novo methylation is that transcription across differentially methylated regions (DMR) seems to be required for the establishment and maintenance of maternal imprinting marks during oogenesis. Analysis of DNA methylation patterns in mouse oocytes using the technique of reduced representation bisulfate sequencing (RRBS) indicated that approximately, 1600 CpG islands undergo DNMT3A/Dnmt3L-dependent methylation in mature oocytes. Interestingly, these CpG islands were found to be preferentially located within active transcription units, lacking histone H3 trimethylated at lysine 4 (H3K4me3), a histone mark associated with transcriptional control. Moreover, H3K4me3 is found enriched at unmethylated CpG islands in embryonic stem cells, consistent with the notion that establishment of DNA methylation at imprinted loci during oocyte growth may be linked with active transcription across the differentially methylated regions of specific imprinted genes (Smallwood et al., 2011; Chotalia et al., 2009). The role of transcription in the establishment of DNA methylation marks during oogenesis is not fully understood. However, it has been suggested that it may be required to maintain an open chromatin configuration and allow the recruitment of de novo methylases to regulatory sequences (Chotalia et al., 2009). Changes in transcription may thus coordinate the progressive establishment of maternal methylation marks with oocyte growth. An important observation emerging from genome wide studies is that methylation patterns during oocyte growth are very dynamic and some methylation marks are not established until the final stages of oocyte growth in preovulatory oocytes (Smallwood et al., 2011),

a stage known to be highly susceptible to both hormonal and/or environmental fluctuations (De La Fuente, 2006) and thus with important clinical implications for assisted reproductive technologies.

Chromatin immunoprecipitation (ChIP) studies to generate genome-wide profiles of histone modifications implicated in promoting or inhibiting DNA methylation have recently revealed that histone methylation plays a critical role in the establishment of DNA methylation marks during oogenesis and suggest that the DNA methylation machinery may 'sense' the status of histone H3 modification at specific regulatory sequences (Stewart et al., 2015). Regulatory sequences destined for DNA methylation in both primary and growing oocytes show reduced H3K4me2 and H3K4me3 while permissive H3K36me3 increases specifically at these sites in growing oocytes. Moreover, analysis of KDM1A or KDM1B knockout oocytes indicates that removal of H3K4me3 is required for the establishment of DNA methylation. Thus histone remodeling in the oocyte is critical to direct de novo methylation (Stewart et al., 2015).

Surprisingly, genome wide DNA methylation studies revealed the presence of CpG methylation at a subset of nonimprinted genes in mammalian oocytes (Rutledge et al., 2014). Studies from several independent laboratories indicate that CpG island methylation during oocyte growth is not exclusively associated with genomic imprinting but it determines a significant proportion of the genomic DNA methylation profile inherited by the preimplantation embryo (Smallwood et al., 2011; Rutledge et al., 2014). Notably, amongst the 1600 methylated CpG islands found in the oocyte, some are associated with imprinted genes, some are required to maintain transcriptional repression at a cluster of testis-specific genes and some are required to repress brain-specific genes during embryonic development (Rutledge et al., 2014). These methylated regions are evolutionarily conserved between mouse and human and may be important to regulate phenotypic changes induced by prenatal and postnatal environmental factors that affect DNA methylation (Rutledge et al., 2014). Consistent with these observations, methylome analysis using genome-wide bisulfite sequencing (DNaseq) confirmed the presence of significant DNA methylation at non-CpG islands in the oocyte genome and suggested that methylation in oocytes seems to occur predominantly over gene bodies (Kobayashi et al., 2012; Shirane et al., 2013). This type of genomic non-CpG methylation is also present in pluripotent stem cells and brain (Shirane et al., 2013; Lister et al., 2009). Remarkably, non-CpG methylation comprises up to 25% of all cytosine methylation in embryonic stem cells (Lister et al., 2009). Analysis of genome-wide methylome maps of mouse oocytes indicates that nearly two thirds of all methyl cytosines in the oocyte genome occur in a non-CpG context and is enriched in gene bodies. Importantly, non-CpG methylation accumulates during oocyte growth (Shirane et al., 2013).

The biological significance of non-CpG methylation in the oocyte genome is not clear at present. However, both the recent discovery of different types of DNA methylation during oogenesis, and the mechanistic insight obtained from genome wide sequencing of the oocyte methylome have now shifted the paradigm from initially considering DNA sequence motifs or structural properties as the potential primary mark for the establishment of specific methylation patterns, to that of the presence of critical histone modifications and transcriptional status at the chromatin template that may nucleate the recruitment of the DNMT3A/DNMT3L complex. Exposure of intragenic regions to DNA methyltransferases during transcription as well as other epigenetic marks that induce an open chromatin structure seems critical in this new model. Thus both transcriptional and epigenetic modifications may be required for Dnmt3L mediated intragenic methylation (Weaver and Bartolomei, 2014; Smallwood et al., 2011; Chotalia et al., 2009). Changes in transcription during oocyte growth may thus coordinate the progressive establishment of methylation marks at different DMRs and may be subject to signaling from granulosa cells at different stages of follicular growth and differentiation as well as hormonal or environmental fluctuations.

Chromatin Remodeling and Chromosome Stability During Oocyte Meiosis

Coinciding with the onset of puberty and following stimulation with the gonadotropin hormone LH, fully-grown mammalian oocytes undergo a process of striking large-scale chromatin remodeling in preparation for meiotic division. A growing body of evidence indicates that this is a critical process with far reaching implications for accurate chromosome segregation and maintenance of chromosome stability.

During mammalian oocyte meiosis, two sequential cell divisions taking place without an intervening S-phase decrease the number of chromosomes to a haploid complement. In order to ensure accurate segregation, meiotic chromosomes exhibit unique structural and functional properties to coordinate the initial segregation of homologous chromosomes (meiosis-I) with the subsequent separation of sister chromatids during meiosis-II. Establishment and timely resolution of centromeric cohesion during this process is under stringent molecular regulation and specialized spindle microtubule attachments at meiosis-I or meiosis-II ensure accurate chromosome segregation patterns (Petronczki et al., 2003; Page and Hawley, 2003).

In preparation for meiotic resumption, preovulatory oocytes exhibit a striking large-scale chromatin remodeling process that is critical to regulate nuclear architecture as well as the dynamics of meiotic progression and chromosome segregation. Large-scale chromatin remodeling is critical for the acquisition of both meiotic and developmental competence in mammalian oocytes (De La Fuente, 2006; De La Fuente et al., 2004a; Yang et al., 2009; Baumann et al., 2010). Growing oocytes are characterized by highly decondensed chromatin and exhibit pericentric heterochromatin domains or "chromocenters" distributed throughout the entire germinal vesicle (GV), a configuration termed "non-surrounded nucleolus" (NSN). In the mouse ovary, growing oocytes exhibit the NSN configuration and show high levels of transcriptional activity, required for the synthesis and storage of maternal transcripts essential to support meiotic resumption and the first cleavage divisions until embryonic genome activation takes place in the fertilized embryo. However, during the final stages of oocyte growth, changes in global chromatin structure result in progressive DNA

condensation and the formation of a perinucleolar heterochromatin rim, termed “surrounded nucleolus” (SN) or karyosphere (De La Fuente, 2006). Importantly, transcription run-on assays demonstrate that large-scale chromatin remodeling into the SN configuration is associated with global transcriptional quiescence. This process is critical to confer full developmental potential and to ensure timely progression of meiotic maturation (De La Fuente, 2006). However, the mechanisms involved remain poorly understood.

A unique experimental system designed for the culture of oocyte–granulosa cell complexes obtained from preantral follicles provided the initial evidence suggesting that a developmentally regulated signal(s), presumably of paracrine origin from granulosa cells modulate chromatin remodeling and transcriptional activity in preovulatory oocytes (De La Fuente and Eppig, 2001). Since then independent laboratories have provided additional evidence to support this model (Liu and Aoki, 2002). Studies indicate that a patent gap junctional communication with granulosa cells is required. However, the signals emanating from granulosa cells that might trigger large-scale chromatin remodeling in the oocyte genome remain to be determined (De La Fuente, 2006). Importantly, evidence obtained from pharmacological manipulation of chromatin structure and several transgenic mouse models indicate that large-scale chromatin remodeling and global transcriptional repression are regulated through different pathways (De La Fuente et al., 2004a; Abe et al., 2010; Andreu-Vieyra et al., 2010; Pattabiraman et al., 2015). For example, in oocytes from nucleoplasmin 2 (Npm2) knockout mice chromatin remains in a decondensed, NSN-like configuration following gonadotropin stimulation. However, global transcriptional silencing takes place in a timely manner (De La Fuente et al., 2004a). On the other hand, oocytes lacking the histone H3K4 methyltransferase (MLL2) or the bromo-domain protein (BRWD1) fail to undergo global transcriptional repression despite large-scale chromatin remodeling from the NSN to the SN configuration (Andreu-Vieyra et al., 2010; Pattabiraman et al., 2015). Moreover, loss of function analysis in vaccinia-related kinase (VRK1) knockout oocytes revealed a critical role for this conserved histone H2A kinase in nuclear chromatin remodeling in preparation for meiotic resumption. Depletion of VRK1 causes striking epigenetic changes, such as loss of histone H2A phosphorylation (H2AT119ph), decreased histone H3 (H3K14ac) and histone H4 (H4K5ac) acetylation. Notably, loss of VRK1 in fully-grown oocytes leads to abnormal chromatin remodeling and a reduced proportion of gametes that exhibit the SN chromatin configuration. Thus, the evidence obtained so far indicates that large-scale chromatin remodeling and global transcriptional silencing in mammalian oocytes are concurrent developmental processes under the control of distinct cellular pathways. Notably, chromatin configuration and subcellular position of the germinal vesicle in fully-grown human oocytes has been suggested to provide a noninvasive marker for the gamete’s meiotic and developmental potential. These findings provide additional support indicating that global chromatin remodeling and the resulting epigenetic landscape acquired following large-scale chromatin remodeling play critical roles in the establishment of meiotic and developmental potential in mammalian oocytes of several species (Ivanovska and Orr-Weaver, 2006).

Establishment, maintenance and/or erasure of covalent histone modifications confers structural and functional identity to distinct nuclear and chromosomal domains (Dundr and Misteli, 2001; Dillon and Festenstein, 2002) and is an essential prerequisite for the control of meiotic chromosome segregation. For instance, while a subset of epigenetic marks, such as histone lysine methylation, remains stably associated with specific chromatin domains (i.e., centromeres) of meiotic chromosomes throughout meiosis (Arney et al., 2002; Liu et al., 2004; Ooga et al., 2008; Meglicki et al., 2008; Swain et al., 2007; Wang et al., 2006), other modifications, such as histone acetylation, exhibit highly dynamic patterns during meiotic resumption and chromosome segregation (Adenot et al., 1997; Kim et al., 2003; De La Fuente et al., 2004b; Sarmiento et al., 2004). High levels of acetylation of histone H3 and H4 at most lysine residues are detectable in the nucleus of fully-grown, preovulatory oocytes. However, concomitant with germinal vesicle breakdown, a wave of global histone deacetylation occurs in the oocyte genome (Kim et al., 2003; De La Fuente et al., 2004b). Although, little is known concerning the enzymatic activities that are involved in this process, recent evidence suggests histone deacetylase 2 (HDAC2) as the major enzyme regulating global histone acetylation levels during oocyte development (Abidi et al., 2004).

Timely coordination of developmental transitions in the global epigenetic landscape during meiotic maturation is of outmost importance for the maintenance of chromosome stability in the female gamete. For example, global histone deacetylation during meiotic resumption is required for the localization and function of centromeric proteins such as ATRX (De La Fuente et al., 2004b) as well as the chromosome passenger complex and interference with this process using the HDAC inhibitor trichostatin A (TSA) results in the formation of hyperacetylated, decondensed chromosomes. Exposure to histone deacetylase inhibitors induce the formation of hyper-acetylated chromosomes with highly abnormal meiotic figures including misaligned chromosomes and chromosome lagging in a large proportion of oocytes (De La Fuente et al., 2004a; Yang et al., 2012). TSA exposure leads to severe oocyte aneuploidy and subfertility (Akiyama et al., 2006). However, several HDAC inhibitors (HDACi) have recently entered phase I and in some instances, phase II clinical trials for the treatment of several types of human cancers (Martinet and Bertrand, 2011). Our recent studies indicate that mammalian oocytes exhibit an extreme susceptibility HDACi-induced chromatin changes even at nanomolar concentrations leading to rapid euchromatin decondensation and severe chromosome instability (Yang et al., 2012). Similarly, functional ablation of HDAC2 in oocytes interferes with deacetylation of H4K16ac and significantly increases the proportion of oocytes with chromosome condensation and segregation errors (Ma and Schultz, 2013). Global histone deacetylation in oocytes is critical for centromere function and binding of chromatin remodeling proteins such as ATRX to centromeric domains as hyperacetylation of chromosomes is sufficient to induce loss of centromeric ATRX (De La Fuente et al., 2004b) and interferes with the deposition of the kinetochore-specific histone variant CENP-A (Ma and Schultz, 2013; Wiens and Sorger, 1998).

Notably, reproductive aging is now widely recognized as a major risk factor for oocyte aneuploidy and oocytes obtained from older mice commonly exhibit histone hyper-acetylation at the metaphase-II stage, in particular of lysine 8 and lysine 12 in histone H4 (Akiyama et al., 2006; Suo et al., 2010). A similar correlation between advanced maternal age, defective deacetylation of the

lysine 12 residue in histone H4 and chromosome misalignment has been detected in human oocytes (van den Berg et al., 2011). In addition, reduced global trimethylation of histone H3 (H3K9me3) as well as dimethylation of histone H4 (H4K20me2) and histone H3 (H3K36me2 and H3K79me2) is associated with highly abnormal chromatin configurations, such as condensed, irregular or clumped chromatin at the GV stage in aged mouse oocytes.

Advanced maternal age was initially associated with meiotic spindle defects (Hassold and Hunt, 2001; Hunt and Hassold, 2008; Vialard et al., 2006). Importantly, microarray analyses of oocytes from young and old mice suggest deregulation of the key mechanisms controlling the spindle assembly checkpoint, kinetochore function, a deterioration of cohesion complexes as well as abnormal chromatin remodeling processes during reproductive aging (Revenkova et al., 2004, 2010; Pan et al., 2008; Hodges et al., 2005; Chiang et al., 2010; Lister et al., 2010) that collectively contribute to age-related subfertility and impaired embryonic development. However, recent studies indicate that the epigenetic maturation of centromeric heterochromatin domains may be particularly susceptible to disturbances leading to detrimental effects on oocyte and embryo quality.

Epigenetic Control of Centromere Function and Chromosome Stability

In the mammalian genome, centromeres are specialized chromosomal domains that form the interface between condensed chromosomes and spindle microtubules (Guenatri et al., 2004; Sullivan and Karpen, 2004). Centromeres contain several megabases of repetitive DNA sequences that are essential, albeit not sufficient for its function. Thus, centromere formation is under strict epigenetic control (Dillon and Festenstein, 2002; Karpen and Allshire, 1997). Several epigenetic marks, such as trimethylation of H3K9 (H3K9me3) and H4K20 (H4K20me3), have been implicated in centromere formation by providing specific docking sites for chromatin remodeling proteins such as heterochromatin protein 1 (HP1) and ATRX (Rea et al., 2000; Lachner et al., 2001; Bannister et al., 2001; Kourmouli et al., 2005; Schotta et al., 2004) (De La Fuente et al., 2004b; McDowell et al., 1999).

The chromatin remodeling protein ATRX (α -Thalassemia mental retardation X-linked) is a member of the SWI/SNF2 family of ATP-dependent chromatin remodeling proteins that is found at the centromeres of mouse and human somatic cells (De La Fuente et al., 2004b; McDowell et al., 1999). ATRX plays an essential role at many critical levels of genome organization in human and mouse somatic cells. In mouse oocytes, ATRX localizes to pericentric heterochromatin in GV stage oocytes. Notably, during metaphase-I and metaphase-II of meiosis ATRX acquires a strict centromeric localization. Analysis of a transgenic mouse model carrying an oocyte-conditional deletion of ATRX revealed that loss of maternal ATRX function results in chromosome misalignment at the metaphase-II spindle and severe centromere instability with a high incidence of DNA breaks in zygote stage embryos. Preimplantation embryos deficient for maternal ATRX exhibit rampant aneuploidy and embryo demise resulting in severe subfertility (Baumann et al., 2010; De La Fuente et al., 2004b). At the molecular level, loss of ATRX function interferes with recruitment of the transcriptional regulator DAXX to pericentric heterochromatin in oocytes and embryos suggesting that ATRX regulates the molecular composition of pericentric heterochromatin during the oocyte to embryo transition (Baumann et al., 2010; De La Fuente et al., 2015). *Atrx* transcripts and protein expression are significantly reduced in oocytes of older mice (Pan et al., 2008; Svoboda et al., 2001). Notably, ATRX-deficient oocytes exhibit the same type of chromosome segregation defects (i.e., premature centromere separation and chromosome lagging) detected in aneuploid oocytes obtained from women of advanced reproductive age (Baumann et al., 2010; Vialard et al., 2006). Thus, transgenic mice with an oocyte-conditional deletion of ATRX constitute an important animal model to determine the mechanisms leading to the transmission of aneuploidy during reproductive senescence and to determine the epigenetic origins of chromosome instability during the oocyte to embryo transition.

Recent studies indicate that a striking 70%–90% of human cleavage stage embryos exhibit one or more blastomeres carrying an aneuploid chromosome complement including deletions and/or translocations (Vanneste et al., 2009; Robberecht et al., 2010; Voet et al., 2011). The mechanisms responsible for such high levels of chromosome instability are not known. However, our ATRX model provides novel evidence indicating that centromeric instability is a major mechanism leading to the formation of large-scale chromosomal rearrangements in the cleavage stage embryo (De La Fuente et al., 2015). In addition, our results indicate that maternal inheritance of ATRX contributes to a striking epigenetic asymmetry of maternal and paternal centromeres that is observed during the transition to the first mitosis. Notably, ATRX is essential for transcriptional silencing of major satellite repeats in the maternal genome and required to prevent deleterious centromeric mitotic recombination events in the cleavage stage embryo (De La Fuente et al., 2015). Loss of ATRX during the critical developmental window of epigenetic reprogramming leads to centromeric breaks, sister chromatid exchanges and large-scale chromosomal rearrangements in a striking proportion of cleavage stage embryos (De La Fuente et al., 2015). These findings suggest that ATRX-deficiency is associated with the formation of mitotic recombination breakpoints and the activation of DNA repair pathways providing a unique model to determine the epigenetic origins of cleavage stage chromosome instability (De La Fuente et al., 2015).

We have also recently observed severe chromosome instability during female meiosis in mice lacking BRWD1 (bromo- and WD-containing protein 1) (Pattabiraman et al., 2015). Proteins that contain functional bromodomains play critical roles in a variety of cellular processes, such as chromatin remodeling and transcriptional regulation, through the recognition of acetyl-lysine residues. Loss of BRWD1 function impairs global transcriptional silencing in preovulatory mouse oocytes, as indicated by transcription run-on-assays, while acquisition of the SN chromatin configuration appeared unaffected (Pattabiraman et al., 2015). Further investigation of the protein coding and noncoding transcriptome by micro-array analysis, pathway-specific PCR arrays as well quantitative real-time PCR revealed surprisingly similar expression patterns of protein coding transcripts in mutants and wild-type oocytes. However, loss of BRWD1 is associated with overexpression of mixed lineage leukemia protein 5 (MLL5) as well as long interspersed

nuclear elements (LINE's), indicating that continued run-on expression in mutant oocytes may be attributable to persistent expression of repetitive elements. Most importantly, BRWD1-deficient ova present highly disrupted meiotic spindle configurations and show a severely limited potential to mature to the metaphase-II stage resulting in complete infertility. Prominent defects in axial chromatid condensation and abnormal chromosome-microtubule interactions lead to major defects in chromosome congression and homologous chromosome separation during anaphase-I and result in severe chromatid elongation with loss of structural integrity and chromatin clumping. Surprisingly, chromosomal breaks and meiotic chromosome decondensation in BRWD1 mutant oocytes are not associated with defects in histone deacetylation, monomethylation of H4K20 or loading of the condensin protein Smc4 (Pattabiraman et al., 2015). While the primary epigenetic defect in this model is not known, it is conceivable that large-scale chromatin remodeling processes are disrupted as a consequence of MLL5 and LINE-1 element overexpression leading to severe chromosome instability.

Notably, it is becoming increasingly clear that the establishment of a proper epigenetic landscape and the epigenetic control of transposon expression during oogenesis are essential mechanisms to ensure normal progression of meiotic transitions and the preservation of genome integrity in the female germ line. For example, overexpression of intracisternal A particle (IAP) transposons in MLL2 knockout oocytes is associated with severe meiotic defects and oocyte DNA damage resulting in premature ovarian failure and female sterility (Andreu-Vieyra et al., 2010). Abnormal expression of the mouse transposon (MTs) in DICER knockout oocytes and mutants of the recently discovered oocyte-specific isoform of DICER (DICERo) exhibit severe meiotic defects with lack of proper chromosome alignment to the meiotic spindle in maturing oocytes (Murchison et al., 2007; Flemr et al., 2013). In addition, targeted deletion of MARF1 (meiotic arrest female 1) during oocyte growth results in overexpression of both IAP transposons and LINE-1 elements resulting in widespread DNA damage and meiotic arrest (Su et al., 2012a, 2012b). Finally, experimental overexpression of LINE-1 elements in mouse oocytes results in oocyte aneuploidy and embryonic lethality (Malki et al., 2014). Elucidating the precise epigenetic mechanisms responsible for predisposing female gametes to aneuploidy and CIN is an important first step towards the identification of reliable early detection markers of chromosome stability, oocyte quality and developmental potential.

Glossary

Atresia The degeneration and death of follicles after they have formed, but before they have fully matured.

Estrous or menstrual cycle A series of cyclical physiological changes occurring in the reproductive organs of a female of the non-primate (estrous) or primate (menstrual) species. The cycle involves intricate endocrine, paracrine and autocrine signals within and between the several tissues in the female including the uterus, ovary, hypothalamus and pituitary glands.

Fertilization The events that occur when a sperm cell penetrates an oocyte and subsequently combine haploid genomes through the process of syngamy to produce a single cell zygote. During normal fertilization, the haploid male and female gametes fuse to produce a diploid zygote. This process can be mimicked in a laboratory culture dish and is known as in vitro fertilization (IVF).

Germinal vesicle breakdown (GVBD) The germinal vesicle refers to the nucleus of an oocyte. When the oocyte resumes meiosis in response to the luteinizing hormone surge that occurs prior to ovulation, the nuclear envelope of the germinal vesicle breaks down in a process known as germinal vesicle break down.

Gonadotrophin hormones These are protein hormones secreted by the pituitary gland, called follicle stimulating hormone (FSH) and luteinizing hormone (LH), that play roles in gamete formation and release.

Luteinization The process by which differentiation of the theca and granulosa cells of the post-ovulatory ovarian follicle results in the formation of a corpus luteum (CL). The result is the production of the steroid hormone progesterone required for maintenance of pregnancy in the event of a successful fertilization.

Non-coding RNA A ribonucleic acid molecule that is not translated into protein, but plays important roles in gene regulation.

Ovulation The process in which an ovarian follicle ruptures and the mature oocyte is released from the ovary into the infundibulum and drawn into the oviduct.

Somatic cell nuclear transfer The process when the diploid nucleus of a somatic cell (found in all organs and tissues within an organism) is used to replace the haploid nucleus of an oocyte to produce a zygote. The organism produced is a clone of the organism that donated the somatic cell.

Steroidogenesis The biochemical process used by cells to produce steroid hormones. The granulosa and theca cells of the developing ovarian follicle produce the steroid hormones, estrogen and progesterone, that are involved in gamete development and pregnancy maintenance, respectively.

Transcription A process in which the genetic information on a strand of DNA is copied into an RNA molecule, by the activity of polymerase enzymes.

Introduction

Oogenesis is an important and complex process in mammals facilitating female gamete development and is regulated by numerous intra- and extra-ovarian factors. The process of oogenesis is dependent on the ovarian follicle, the functional unit of the ovary, and the interaction between the oocyte and the surrounding follicular cells. This cellular association is crucial for the oocyte maturation process as well as for follicle development. The use of knockout models has allowed substantial progress in elucidating the factors regulating oocyte and follicle growth and development, and the signaling pathways involved within these processes. Meanwhile, studies describing the roles of regulatory non-coding RNAs (ncRNA), especially microRNA (miRNA), in oogenesis have recently become an area of increased focus. This article summarizes the various roles of ncRNA in oogenesis, focusing on the better known miRNA regulatory mechanisms, gonadotropin regulation, and oocyte development.

Non-Coding RNA

Non-coding RNA are comprised of two main groups. The long RNA species include long intergenic noncoding RNAs (lincRNAs), long non-coding RNAs (lncRNA), and circular RNAs (cirRNAs). Alternatively, the small RNA species include microRNAs (miRNAs), endogenous small interfering RNAs (*endo*-siRNAs), piwi-interacting RNAs (piwiRNAs), small nucleolar RNA (snoRNA), and transfer RNAs (tRNA). Other non-coding, structural RNAs include ribosomal RNAs (rRNAs) and nuclear RNAs that can often be longer than 200 nucleotides.

Biogenesis of Non-Coding RNA

Small regulatory ncRNA differ in origin, length and Argonaute protein partners through which they elicit their biological function. Both miRNA and *endo*-siRNA are processed from double-stranded precursors that eventually results in 20–22 nucleotide mature small RNA. Alternatively, piRNA are generated from long single-stranded precursors into 26–31 nucleotide functional molecules in a Dicer-independent manner.

MicroRNA can be produced following transcription and processing from their own genes in addition to being processed from the introns or exons of host genes. MicroRNA have two biogenic pathways through which they are produced, canonical and non-canonical. MicroRNA are first transcribed as primary miRNA (pri-miRNA) by RNA polymerase II, and based on sequence complementation within the RNA molecule, secondary RNA structures producing 60–75 nucleotide (nt) hairpins occur within the pri-miRNA. The hairpins are recognized by DGCR8 (DiGeorge syndrome critical region 8), which directs the RNase III enzyme Drosha to cleave the base of the hairpin resulting in a pre-miRNA. Once the pre-miRNA reach the cytosol, they are cleaved by Dicer (an RNase III enzyme) in complex with transactivating response element RNA-binding protein (TRBP), resulting in a functionally mature miRNA. It is the mature miRNA that are capable of being loaded into an RNA induced silencing complex (RISC) and utilized for post-transcriptional gene regulation (PTGR) (Fig. 1).

The biogenesis and mechanism of the piRNA class is less understood than miRNA and *endo*-siRNA. Piwi-interacting RNA are cleaved from long single-stranded RNA precursors in a Dicer independent mechanism. Mature piRNA are approximately 26–31 nt long, and are expressed primarily in germ cells. Long noncoding RNA (lncRNA) are described at their most basic definition as RNA pol II transcribed ncRNA that are greater than 200 nucleotides in length, and they have a role in regulating a diverse range of cellular processes.

Mode of Action of Non-Coding RNA

Following Dicer cleavage, miRNA and *endo*-siRNA interact with the family of Argonaute proteins (AGO1–4) to cause the association of RISC machinery. An Argonaute protein associated with either a miRNA or *endo*-siRNA interacts with target mRNA via

Fig. 1 MicroRNA biogenesis is initiated via the activity of RNA polymerase II resulting in synthesis of a primary miRNA transcript (Pri-miRNA) that is both capped and polyadenylated. The appropriate spatial complementation of specific nucleotides within the transcript results in the formation of hairpin secondary structures that are recognized by the RNA processing complex consisting of DROSHA and DGCR8. The enzymatic activity of this protein complex results in cleavage and removal of the hairpin structure (now considered a pre-miRNA) from the primary transcript. Exportin 5 facilitates the transport of pre-miRNA from the nucleus into the cytoplasm of the cell where it is recognized by Dicer, and the loop is cleaved leaving a short duplex mature miRNA molecule. Upon dissociation, either strand from the duplex miRNA structure can be utilized by the RNA-induced silencing complex to contribute to posttranscriptional gene regulation through impacting mRNA stability and/or translation efficiency in addition to contributing to chromatin modifications to control gene expression. This image is used with permission from Springer Publishing.

complementarity between the small single-stranded RNA molecule and the 3' untranslated region (UTR) of the target mRNA. If complete complementarity exists between the small RNA molecule and target mRNA 3'UTR, then cleavage of the target mRNA can occur. If the complementarity is incomplete the primary mechanism of PTGR occurs through suppression of translation by influencing mRNA interaction with the translational machinery.

PIWI proteins are found to be located in nuclear and/or perinuclear nuage, a structure where piRNA can function to repress genetic elements. The PIWI proteins have an N-terminal PAZ domain followed by the MID (middle) domain, which together recognize and bind the 3' end of piRNA molecules.

Oogenesis

Development of the mammalian oocyte (Fig. 2) begins during fetal life through proliferation of primordial germ cells by mitosis. Mammals are born with a finite number of oocytes that originate from a primordial germ cell pool following migration to the genital ridge during embryonic development. Oogenesis begins with the breakdown of germ cell clusters and the formation of primordial follicles. The oocyte associates with granulosa cells to form primordial follicles that remain arrested in prophase I of meiosis. At puberty, the oocyte in the primordial follicle is triggered to grow under the influence of gonadotropin hormones. It then undergoes numerous molecular and morphological changes in its follicular cell milieu. This process of follicular development is controlled by closely coordinated endocrine and paracrine factors contributed by the developing oocyte and surrounding granulosa and theca cells. In turn, this process is controlled by multiple genes whose expression and interactions are tightly regulated in the oocyte, granulosa and theca cells. Following recruitment and selection, maturing oocytes undergo germinal vesicle breakdown (GVBD) facilitating the progression through meiosis until arrest at metaphase II in most domestic animals. Following GVBD the oocyte is transcriptionally quiescent until after fertilization and the activation of the embryonic genome occurs around the two- to eight-cell stage of development depending upon the species. Distinct sets of transcripts are present in female germ cells, with some maternal mRNAs being translated in the germline to support oocyte formation and maturation, while others are stored in the oocyte and translated during early embryogenesis. Post-transcriptional gene regulation via small ncRNAs has emerged as one of the most important mechanisms to control gene expression in the germline cell and its various developmental stages.

Fig. 2 Oogenesis in mammals begins in the fetal stage. Primordial germ cells colonize the ovary and eventually undergo breakdown of germ cell clusters. The oocyte along with its surrounding granulosa cells forms the primordial follicle, which is arrested in prophase I at birth. At puberty, the active hypothalamus–pituitary–gonadal axis facilitates the development and maturation of follicles and the oocyte within. During the cycle, oocytes within maturing follicles eventually undergo germinal vesicle breakdown and will progress through meiosis until arrested in metaphase II concomitant with ovulation. Meiosis in the oocyte is completed upon fertilization by the sperm. The consequent embryo generates its own set of primordial germ cells that colonize the developing gonads.

Role of Noncoding RNA in Primordial Germ Cell Migration, Development, Specification and Sex Determination

Gametogenesis in mammals begins from primordial germ cells (PGC) that colonize the mesonephros of the developing mammalian embryo and eventually give rise to the testis or ovary. The newborn ovary contains a limited number of oocytes, and with each estrous (domestic animals) or menstrual cycle (primates), a given number of primary oocytes are recruited although only some will undergo maturation and ovulate. The process of gonad formation (in either sex) and oocyte development and maturation is characterized by significant changes in the gene expression profiles. Small regulatory molecules such as miRNA and *endo*-siRNA are present in germ cells and play crucial roles in the regulation of various events in the life of germ cells, including the specification of germ cells, migration and gonad colonization, protection and/or alteration of the genome, and sex-specific differentiation into competent gametes.

Across mammalian species, PGCs migrate to the gonad, begin to associate with somatic cells and commit to a sex-specific fate. MicroRNA clusters which promote cell cycle progression are crucial for primordial germ cell migration, defects of which cause significant reduction in the number of PGCs colonizing the embryonic gonads. Dysregulation of miRNA activity does not specifically affect PGC specification or migration but does affect the ability of PGCs to proliferate and survive during migration, thus resulting in lower number of PGCs colonizing the fetal gonads. Females that fail to compensate for this loss of PGC migration and specification undergo premature ovarian failure and are often sterile. Conversely, somatic cell loss of small RNAs in mice, results in establishment of larger pool of primordial follicles in the neonate ovary, but these mutants are infertile due to premature follicle maturation and loss of oocytes resulting from defects in granulosa cells.

Once PGCs arrive in the gonad, they begin to commit to their sex-specific fate and are highly regulated by their somatic cell niche environment. MiRNA expression profiling of PGCs colonizing the gonad reveals differential expression patterns of miRNAs between the sexes, and hence points towards miRNA regulation of sex specific PGC differentiation. Differential expression of miRNAs was detected when comparing male and female PGCs in mice, sheep and pig. Primordial germ cell specification in mammals involves the silencing of genes associated with somatic cell differentiation and activation of germ cell-specific genes. During early PGC development and specification, miRNAs are highly dynamic in their expression. This is especially important during the period of transcriptional arrest due to higher gene regulation needs.

Role of Noncoding RNA in Pre-pubertal Oogenesis

MiRNAs are involved in the entire process of ovarian follicle development, including follicle growth, atresia and ovulation. A majority of follicles undergo atresia during folliculogenesis. Differentially expressed miRNAs in healthy, early atretic, and progressively atretic follicles signify the roles of miRNAs in regulating follicle development and atresia. In each stage of follicle development, different growth factors contribute to stage-specific functions in different cell types of the follicle. Various studies have shown that miR-21, miR-125b, let-7a and let-7b are the most abundantly expressed miRNAs across the different follicular development stages. Moreover, mouse postnatal ovaries show dynamic changes of miRNA profiles during specific stages indicating their roles at the different phases of ovarian development. Once females reach sexual maturity, oocytes arrested at prophase I of meiosis are recruited in small numbers by gonadotropin hormones (FSH and LH) to produce mature follicles, and are now exposed to a different milieu of miRNAs.

Role of Noncoding RNA in Post-pubertal Oogenesis

The ovarian follicle is the functional unit of the ovary and comprises of the oocyte and its surrounding follicular cells. Maturation of the oocyte begins at puberty and involves maturation of the entire follicular unit, when primordial follicles in their resting stage, are activated to start development. The different developmental stages of the follicle such as primary, secondary, preantral and antral follicles have between one to more than five layers of cuboidal granulosa cells (Fig. 3). The secondary follicle and later stages also have theca cells that form a layer around the oocyte-granulosa complex. At the antral stage, follicles become gonadotropin-dependent and form large Graafian follicles that eventually ovulate under the influence of these gonadotropins.

Effect of gonadotropins on miRNA expression in the ovary

Oogenesis is tightly regulated by pituitary gonadotropins, viz., follicle stimulating hormone (FSH) and luteinizing hormone (LH). Well-synchronized, sequential actions of FSH and LH are critical for follicle growth and pre-ovulatory steroidogenesis, leading to successful ovulation. The cross-talk between ncRNA and gonadotropins has been shown in numerous studies, wherein FSH and LH modulate miRNA expression in ovarian cells. During folliculogenesis, the expression of miR-143, let-7a and miR-15b is negatively regulated by FSH. Studies show FSH changes miRNA expression in in vitro cultured rat granulosa cells and ovarian cell line. The ovulation inducing LH surge increases miR-122 expression in the rat ovary and miR-21, miR-132 and miR-212 in the granulosa cells of the mouse ovary. Though both in vivo and in vitro studies have shown that FSH and LH can affect miRNA expression patterns in ovarian cells, how these gonadotropins modify miRNA expression and how this cross-talk regulates ovarian function still needs investigation.

Role of ncRNAs on oocyte development and maturation

The inability to transcribe mRNA during the final stages of oocyte development and potential for PTGR has led numerous laboratories to pursue the characterization of the ncRNA expressed in the maturing oocyte. The function of miRNA and associated enzymes

Fig. 3 The ovarian follicle is the functional unit of the ovary. At puberty, under the influence of gonadotropins, the oocyte and its surrounding follicular cells, begin maturation. The primordial follicles in their resting stage are activated to develop into the primary, secondary, preantral and antral follicles. A majority of developing follicles undergo atresia and progress no further. The follicles that successfully continue through the maturation stages, add on granulosa cells that surround the developing oocyte. The later stages also have theca cells that form a layer around the oocyte-granulosa cell unit. The large Graafian follicles eventually ovulate under the influence of pituitary gonadotropins in each reproductive cycle, to form the corpus luteum. This structure enables pregnancy maintenance if the ovulated oocyte is successfully fertilized to form an embryo. In the absence of a viable embryo, the corpus luteum degenerates and the entire process of follicular maturation is repeated in the next reproductive cycle.

within the developing oocyte were determined using oocyte-specific knock out models. Results show loss of *Dicer* has an observable effect on oocytes and both biogenic enzymes are required for healthy oogenesis. Similarly, use of RNA interference knockdown of *Dicer1* in GV stage mouse oocytes significantly decreases both the proportion of oocytes reaching the MII stage and the expression of dicer protein-dependent miRNAs. Using the same knockout system, it was shown that oocyte-specific deletion of *Drosha* demonstrated no discernible phenotypic change. And that *Dgcr8*, a RNA-binding protein critical only for the canonical miRNA biogenesis pathway, is not required for the maturation of mouse oocytes. Collectively, these results suggest that miRNA produced via the canonical pathway in the oocyte are not required for the production of phenotypically normal oocytes in mice.

Endo-siRNA, on the other hand, might have a more critical role in oocyte development and maturation. MicroRNAs and siRNAs silence gene expression post-transcriptionally by guiding an Argonaute protein to their targets. Catalytically inactive knock-in allele of *Ago2* (*Ago2ADH*) in which the catalytic DDH motif is mutated to ADH, inhibiting endonucleolytic cleavage without affecting small RNA binding and disrupts the function of *endo*-siRNAs in oocytes. Oogenesis and hormonal response are normal in *Ago2ADH* oocytes, but meiotic maturation is impaired, with severe defects in spindle formation and chromosome alignment that lead to meiotic catastrophe. In pig oocytes, a microinjection technique to knockdown *DICER* reduces the proportion of oocytes that develop to meiosis II (MII) stages and was significantly lower than oocytes with *DROSHA* and *DGCR8* deficiency.

Role of ncRNA in granulosa cumulus cells

Granulosa cell proliferation and function are essential in follicle development, maturation, and atresia. Several miRNAs are known to regulate granulosa cell proliferation, steroidogenesis and apoptosis. Conditional knockout mouse models help us understand miRNA function in granulosa cell development and oogenesis. Deletion of *Dicer1* results in female sterility and multiple reproductive defects though *Dicer* deficient female mice display normal mating behavior and embryo quality. Comparative analysis of the ovarian tissue from 8-day, 8-week and 8-month old conditional *Dicer1* deleted and wild type mice, showed increased primordial follicle pool endowment, accelerated early follicle recruitment and more degenerate follicles in the *Dicer1* knockout mice. Furthermore, the genes involved in follicle development showed significantly different expression between the *Dicer1* and wild-type mouse ovaries. Female infertility was also the major phenotype observed in a *Dicer1* depletion model and the CL had reduced vascularization. These results together suggest that miRNAs are important regulators of female reproductive tract development and fertility.

Role of ncRNA on regulation of steroid biogenesis

The growth and development of the oocyte is dependent on its bidirectional cross-talk with the surrounding cumulus or granulosa and theca cells. Granulosa and theca cells facilitate steroidogenesis which is critical for successful ovarian folliculogenesis, ovulation, luteogenesis, and oocyte maturation. MicroRNA mediated regulation of steroidogenesis in granulosa cells also potentially affects oocyte maturation. Though no direct studies have implicated a role for ncRNA in theca cells, miRNA function in granulosa cells has been evaluated with different conditional knock out models and in vitro experiments. In an in vitro human granulosa cell culture system treated with miRNA precursors, miRNAs have been shown to enhance or inhibit ovarian progesterone, androgen and estrogen synthesis. Moreover, overexpression of miR-378 decreases estradiol production by regulating aromatase in porcine

granulosa cells, and miR-34a and miR-320 inhibit estradiol release from human granulosa cells and murine ovaries, respectively. In contrast, overexpression of miR-132 promotes estradiol synthesis in mouse granulosa cells via translational repression of Nuclear receptor related 1 (Nurr1). Similarly, overexpression of miR-383 enhances estradiol release from granulosa cells by targeting RBMS1. Recent results show that overexpression of miR-378 in porcine cumulus cells suppress oocyte maturation and embryo developmental potential by inhibiting aromatase expression. Overexpression of miR-224 of cumulus cells leads to the impairment of cell expansion and correlated gene expression, further delaying oocyte maturation and decreasing oocyte developmental potential. Besides the effects on steroidogenesis, miRNA also regulate granulosa cell proliferation and apoptosis.

Ovulation and luteinization

Though the stage-specific expression of miRNAs in the corpus luteum (CL) has been reported, miRNA function in the processes of ovulation and luteal tissue formation, maintenance, rescue or regression is poorly understood. Only few functional studies have been conducted on miRNA in the CL. Microarray analysis of differentially expressed miRNAs in non-regressed and regressed bovine CL shows that miRNA-378 may suppress luteal cell apoptosis by targeting the interferon gamma receptor 1 gene. Moreover, miR-34a expression increases during the follicular to luteal transition in cattle and sheep. Increasing the concentration of miR-34a in in vitro cultured luteal cells results in an increase in progesterone production and decrease in proliferation of steroidogenic cells, which could be due to miR-34a inhibition of both Notch1 and YingYang1 (YY1). *Neat1* is a lncRNA species that has a higher expression level in luteal tissue. *Neat1* knockout mice show CL dysfunction concomitant with reduced progesterone production, thus leading to decreased fertility despite normal ovulation.

Dysregulation of Noncoding RNA Impacting Oogenesis

Abnormal expression of ovarian miRNAs has been associated with numerous reproductive tract disorders. Misregulation of germ cell development at any stage can have deleterious outcomes in oogenesis. MicroRNA have been detected in human and bovine IVF culture media, and differential expression correlated with embryo quality and pregnancy outcomes. MicroRNA expression can also be utilized to explain low cloning efficiency and the high incidence of abnormalities in embryos produced via somatic cell nuclear transfer (SCNT). These biomarker miRNA can also be used to evaluate oocyte competence which is known to decline with ovarian age. Characterization of miRNA impacted by age of the female would be a valuable resource to better understand the biology of aging oocytes and consequent genetic abnormalities. A similar situation is observed in cases of premature ovarian failure (POF), which is characterized by a reduced follicle pool and follicular dysfunction in the ovary manifesting with endocrine and reproductive disorders. The mouse knock-out models for Dicer and Drosha have shown compromised folliculogenesis and defective meiosis, CL insufficiency, POF, and infertility in the adult ovary. Studies have also correlated POF with dysregulated expression of miRNAs in serum and plasma. Corpus luteum insufficiency associated with miRNA dysregulation is also seen in cases of PCOS and obesity. Although the clinical and biochemical signs of PCOS are typically heterogeneous, abnormal folliculogenesis is considered a common characteristic. Aberrant expression of several miRNA has been correlated with the PCOS phenotype, including roles in carbohydrate metabolism, pancreatic beta cell function, insulin resistance and steroid synthesis. These differentially expressed miRNAs are also involved in various signaling pathways that regulate hormone and energy metabolism. This involvement in hormone regulation was shown in a dihydrotestosterone induced rat PCOS model.

It is now also accepted that the miRNAs involved in early embryogenesis share functional similarities in the process of cancer development. These miRNAs can act as tumor suppressors but can also be oncogenes. Multiple studies have identified strong marker miRNA for the different types and stages of ovarian cancer in humans. Furthermore, studies show that tumor cells, derived from effusions of ovarian cancer patients, reflect a distinct miRNA expression signature, associated to metastatic progression. These circulating miRNA have the potential to be specific biomarkers and possibly prognostic aids.

Conclusion

Several studies have revealed preferential expression of miRNAs in the ovary of different species, signifying that they have an important role in ovarian functions. Better understanding of the molecular basis of ncRNA function in oogenesis has provided valuable insight into mammalian reproduction. Oogenesis is a well-coordinated process involving molecular cross-talk between the various somatic cell types and the developing gamete in the follicle. MicroRNA have a definite, synergistic function in the cross-talk between these cell types and the specific regulatory mechanism in the follicle development process. Our increasing understanding of oogenesis, miRNA regulatory networks and the advances in detection, analyses and correlation of miRNA expression specific to ovarian events will help pave the way for newer diagnostic, prognostic and therapeutic strategies for improving female reproductive ability.

Introduction

Generation of a haploid nucleus is achieved by the two gametes, oocyte and sperm, during the meiotic cell cycle. Unlike in sperm, meiosis in oocytes is a protracted process, initially arrested at the diplotene stage of the first prophase. Meiotically-arrested oocytes are characterized by diffuse chromosomes surrounded by a nuclear membrane known as germinal vesicle (GV). Reinitiation of meiosis involves dissolution of the nuclear membrane, referred to as germinal vesicle breakdown (GVB), chromosome condensation, formation of the spindle of the first metaphase (MI) and its migration to the oocyte cortex, along with chromosomes segregation. Oocytes complete the first meiotic division by elimination of one set of homologous chromosomes and the formation of the first polar body (PBI) that is immediately followed by their maturation into unfertilized eggs, arrested at the second meiotic metaphase (MII). The ready to be fertilized MII oocytes are released from the ovarian follicle into the oviductal ampulla during ovulation. The meiotic cell cycle in the oocyte is not concluded before fertilization; sperm penetration triggers the segregation of sister chromatids and the extrusion of the second PB (Fig. 1). This chapter summarizes our present knowledge related to the control of meiosis in oocytes with a particular focus on the mechanisms underlying PBI extrusion. Improper execution of the first meiotic division is a major cause for aneuploidy that might result in severe genetic malformations (Hassold and Hunt, 2001).

Regulation of Meiosis in Oocytes

Resumption of meiosis in the oocyte is regulated by intracellular levels of cAMP (Cho et al., 1974; Dekel and Beers, 1978). Unlike most cellular systems, in which the concentrations of cAMP at any given moment represent the balance between its synthesis and degradation, the major contribution of this inhibitory nucleotide in oocytes is uniquely attained by gap junctional-mediated supply from the cumulus/granulosa cells (Dekel et al., 1981). Furthermore, degradation of cAMP, performed by the oocyte specific phosphodiesterase 3A (PDE3A), is predominantly regulated by the transfer of the PDE3A inhibitor, cGMP, from this same somatic compartment of the ovarian follicle (Vaccari et al., 2009). As maintenance of meiotic arrest is heavily dependent on established cell-to-cell communication, it is the closure of gap junctions within the ovarian follicle, mediated by luteinizing hormone (LH), which stimulates the oocyte to resume meiosis (Dekel et al., 1981; Sela-Abramovich et al., 2005; Sherizly et al., 1988; Norris et al., 2008). This response to LH stops the transfer of both cyclic nucleotides, cAMP and cGMP, relieving meiotic arrest.

Fig. 1 The master regulator of meiosis in oocytes, CDK1 is activated upon its heterodimerization with cyclin B1. The activity of CDK1 is elevated at reinitiation of meiosis, reaching its maximum at MI. A sharp drop follows this rise in CDK1 activity that occurs due to degradation of cyclin B1 executed by the proteasome and mediated by E3, also known as APC/C. This enzyme decorates cyclin B1 by a polyubiquitin chain, tagging it for degradation.

Cyclin Dependent Kinase (CDK1)

The master regulator of meiosis in oocytes is the cyclin dependent kinase (CDK1), an enzyme that is activated by a series of phosphorylation-dephosphorylation events followed by its heterodimerization with cyclin B1. Activation of CDK1 at the onset of meiosis is inhibited by cAMP (Choi et al., 1991; Fulka et al., 1992). This inhibitory effect of cAMP on CDK1 activation is achieved by the prevention of CDK1 dephosphorylation (Choi et al., 1991; Goren and Dekel, 1994) combined with the inhibition of cyclin B1 synthesis, minimizing its availability (Hampl and Eppig, 1995). Upon the response of the follicle to LH, intraoocyte levels of cAMP drop allowing both, CDK1 dephosphorylation and cyclin B1 accumulation. The resulting activated CDK1 then stimulates reinitiation of the meiotic division (Fig. 1).

Reinitiation of meiosis is characterized by chromosome condensation and the alignment of pairs of homologous chromosomes on the equator of a centrally localized MI spindle. Upon entry into anaphase, characterized by homologous chromosome separation, the MI spindle migrates to the oocyte periphery. The first meiotic division is completed by cytokinesis, and culminates by the formation of PBI. The extrusion of PBI is immediately followed by entry of the oocyte into MII (Fig. 1). Metaphase to anaphase transition and PBI extrusion is absolutely dependent on CDK1 inactivation (Choi et al., 1991; Hampl and Eppig, 1995; Hashimoto and Kishimoto, 1988).

Lowering the activity of CDK1 prior to PBI extrusion is subsequent to degradation of cyclin B1, which is subjected to regulation by the ubiquitin–proteasome pathway. In addition to cyclin B1, this machinery is also responsible for the elimination of securin (Hagting et al., 2002). Proteasomal degradation of securin relieves its inhibitory effect on separase activity allowing the cleavage of the cohesion molecules and resulting in disassociation of pairs of homologous chromosomes (Kudo et al., 2006; Terret et al., 2003; Herbert et al., 2003; Holland and Taylor, 2006).

Degradation of these regulatory proteins, executed by the proteasome–ubiquitin pathway is mediated by particular E2s, such as E2C, E2S and E2D3 (Ben-Eliezer et al., 2015) and the specific E3, also known as APC/C (Jones, 2011). These enzymes decorate protein substrates by a polyubiquitin chain, thus tagging them for degradation (Karabinova et al., 2011; Wickliffe et al., 2009). Upon inhibition of the proteasome and prevention of CDK1 inactivation oocytes arrest at MI and fail to extrude PBI (Terret et al., 2003; Herbert et al., 2003; Ben-Eliezer et al., 2015; Josefsberg et al., 2000; Pomerantz et al., 2012). Interestingly, inactivation of CDK1 along with proteasomal inhibition allowed the extrusion of PBI (Pomerantz et al., 2012). These findings suggest that inactivation of CDK1 is not only necessary but also sufficient for PBI formation (Fig. 2).

Entry into the second meiotic division is dependent on reactivation of CDK1 that is made possible due to another round of cyclin B1 synthesis. The elevated activity of CDK1 keeps the oocytes arrested at metaphase II (Fig. 1).

The MAPK Signaling Pathway

The MAPK pathway represents a sequential phosphorylation events executed by MAPK kinase kinase (MAP3K), MEK, and ERK (Shaul and Seger, 2007). The upstream regulator of MEK in oocytes is MOS (Goldman et al., 1987). It has been shown that activated ERK takes part in the formation of the contractile ring responsible for cytokinesis in pig oocytes (Lee et al., 2000), however, this was not confirmed in mice (Hatch and Capco, 2001). Nevertheless, strong evidence for a role of MAPK pathway in regulating the asymmetric cell division, characteristic to PB formation, has been reported. Activation of the MAPK pathway, taking place in oocytes extruding PBI (Verlhac et al., 1994), affects microtubules dynamics (Verlhac et al., 1996) and is necessary for localization of ERK

Fig. 2 Extrusion of PBI consists of cytokinesis and chromosome segregation, both subjected to the control of proteasomal degradation. One protein target for the proteasome is cyclin B1, the degradation of which leads to CDK1 inactivation and cytokinesis, whereas degradation of securin brings about chromosome segregation. CDK1 inactivation along with proteasomal inhibition, allowed PBI formation by a mechanism that apparently involves direct activation of separase.

and MEK1/2 on the spindle poles and its migration. Along this line, ablation of the upstream c-mos resulted in inhibition of spindle migration (Verlhac et al., 2000), altered cleavage plane and the production of an abnormally large PBI (Choi et al., 1996). Knocking down GM-130, a *cis*-Golgi protein, colocalizing with phosphorylated MEK at the spindle poles, resulted in the extrusion of a large PBI and elongated spindle (Zhang et al., 2011). In agreement with the role of MAPK pathway in spindle formation, it has been shown that inhibition of MEK1/2 during the first anaphase prevented the contraction of the spindle microtubules and reduced its length (Pomerantz et al., 2012).

Spindle Migration

Extrusion of PBI represents a particular case of asymmetric cell division. This phenomenon is achieved upon localization of the spindle at the cell periphery. Several studies have shown that the central spindle is involved in the positioning of the cleavage furrow (Bonaccorsi et al., 1998; Glotzer, 2005; Rappaport, 1985); therefore, an off-center spindle leads to asymmetric division as occurs during meiosis in oocyte. As mentioned previously reinitiation of the first meiosis is characterized by GVB immediately followed by chromosome condensation (Fig. 1). Concomitantly, a massive organization of microtubules around the chromosomes leads to the formation of a bipolar spindle (Schuh and Ellenberg, 2007). At metaphase of the first round of meiosis, the spindle is centrally localized (Longo and Chen, 1985). It is only later, towards the extrusion of PBI that the spindle migrates to the oocyte cortex (Schuh and Ellenberg, 2008). Once the spindle reached the cortex its axis is arranged at the appropriate orientation to certify the correct separation of the pairs of homologous chromosomes between the oocyte and PBI, establishing the conditions for an asymmetric cell division.

The meiotically-arrested oocyte is covered by a dense population of microvilli. Once the spindle approaches the oocyte periphery these microvilli disassemble (Longo and Chen, 1984; Tremoleda et al., 2001). In addition, actin filaments (F-actin) become denser and accumulate under the oocyte membrane to form the “actin cap” (Schuh and Ellenberg, 2008; Longo and Chen, 1984; Tremoleda et al., 2001). Actin microfilaments are key players in the completion of spindle migration (Longo and Chen, 1985; Maro et al., 1986). The major member of the actin family that regulates the spindle formation is FORMIN2 (Dumont et al., 2007a). FORMIN2 null oocytes fail to position the metaphase spindle during meiosis I and do not form PBI (Leader et al., 2002). A later study showed that FORMIN2 null oocytes failed to extrude PBI also due to mislocalization of myosin II (Dumont et al., 2007a). Myosins are actin-associated motor proteins that surround the F-actin in the cortex. By forming an actomyosin ring, myosins participate in spindle migration (Brunet and Maro, 2005). Myosin 2 was found to concentrate on the spindle poles (Simerly et al., 1998) and myosin 10, the transcripts of which are abundant in mouse oocytes (Evsikov et al., 2006), is necessary for spindle anchoring to the cortex (Weber et al., 2004). Myosin activation occurs by myosin light chain kinase (MLCK, Simerly et al., 1998), which is regulated by MAPK and its upstream c-mos (Brunet and Maro, 2005). The deletion of c-mos prevents the translocation of the spindle to the oocyte cortex, resulting in an altered cleavage plane and subsequent formation of an abnormally large polar body (Choi et al., 1996). The chromosomes themselves also regulate spindle migration and cortical organization, even in the absence of microfilaments (Maro and Verlhac, 2002). This ability of the chromosomes is attributed to RAN, a small GTPase (Dumont et al., 2007b). Upon reinitiation of meiosis, a gradient of GTP-bound RAN (RAN-GTP) is formed around the chromosomes (Zheng, 2004). This gradient is generated due to the localization of its nucleotide exchange factor RCC1 on the chromatin and the diffusion of GTPase activating protein throughout the cytoplasm.

Chromosome Segregation

Unlike the mitotic and the meiotic MII, where sister kinetochores should oppose each other to segregate to different poles, at MI, sister kinetochores must organize and orient side by side to the same pole (Brar and Amon, 2008), requiring sequential loss of cohesion between the chromosomes. The cohesion between the chromosomes is sustained by cohesin, a multi-unit protein, which includes rec8. Chromosome separation at the first anaphase uniquely requires the removal of cohesion, which is, restricted to the chromosome arms, while maintaining the association between sister chromatids (Brar and Amon, 2008). As mentioned previously, the proper chromosome segregation at the end of MI and the extrusion of one set of chromosomes with PBI, is regulated by proteasomal degradation of securin (Hagting et al., 2002). Securin is an inhibitor of separase, an enzyme that cleaves rec8 on chromosome arms, leading to cohesion removal, resolving the chiasmata and allowing homologous chromosome segregation (Kudo et al., 2006; Terret et al., 2003). The cohesion at the centeromeres remains unharmed at MI, guarantying that sister chromatids stay attached until the second metaphase (Terret et al., 2003; Zou et al., 1999).

As mentioned previously, cyclin B1 degradation and the CDK1 inactivation are necessary for PBI extrusion. Inactivation of CDK1 is apparently also critical for chromosomes segregation. The CDK1-cyclin B1 complex binds the phosphorylated separase (Holland and Taylor, 2006; Gorr et al., 2005), thus preventing separation of the homologous chromosomes, blocking PBI extrusion (Gorr et al., 2006). Indeed, expression of non-degradable cyclin B1 in oocytes inhibits chromosome segregation (Herbert et al., 2003). Similarly, pharmacological inactivation of CDK1 along with proteasomal inhibition allowed the extrusion of PBI (Pomerantz et al., 2012).

Protein Degradation: The Ubiquitin–Proteasome Pathway

Oocytes treated with a proteasome inhibitor arrest at MI, exhibiting aborting attempts to extrude PBI (Josefsberg et al., 2000). As mentioned previously, the cellular signal for protein degradation is provided by substrate polyubiquitination. This posttranslational modification is facilitated by a three sequential step-operation executed by a multiple enzyme system as follows. The initial binding of ubiquitin by the ubiquitin-activating enzyme E1 is proceeded by its transfer to a ubiquitin-conjugated enzyme, E2 and completed by its relocation to the substrate via E3, the ubiquitin protein ligase, also known as APC/C (Karabinova et al., 2011; Wickliffe et al., 2009).

The APC/C is a protein complex, the main co-activator of which in meiosis is CDC2 (Peters, 2006). At MI, the APC/C^{CDC20} complex targets securin and cyclin B1 for degradation thus allowing PBI extrusion (Fig. 1) (Reis et al., 2007). The APC/C activity is rigorously regulated during cell division to avoid cell cycle progression prior to the completion of chromosomes condensation and their proper alignment on the spindle equator. This strict regulation is achieved by the spindle assembly checkpoint (SAC), an array of proteins including Mad1, Mad2, Bub1, Bub3, BubR1 and Mps1. This checkpoint ensures that the APC/C activation does not occur before all the kinetochores are properly connected to the spindle. Once the alignment of all chromosomes is accomplished, SAC is released, inhibition of APC/C activity is removed, cyclin B1 and securin are degraded and PBI is extruded (Homer et al., 2005; Leland et al., 2009). Cyclin B1 and securin are the major proteins degraded by the proteasome. However, numerous other meiotic proteins such as Cdc20, Cdc25, Polo-like kinase (PLK-1), ECT2 and C-MOS are subjected to proteasomal degradation (Karabinova et al., 2011).

Ubiquitin, a 76 amino acid polypeptide entails seven lysines, each one of which serves as the acceptor site for the next ubiquitin attachment. The type of ubiquitin signal depends on the lysine residue the chain is assembled on (Hershko and Ciechanover, 1998). Chains linked on lysine48 (K48) signal for degradation whereas linkage on K63 usually signals for DNA repair, inflammation and more (Wickliffe et al., 2009). Mitotic substrates, including APC/C substrates were demonstrated to be tagged for degradation by K11 chains (Jin et al., 2008; Kirkpatrick et al., 2006). Ubiquitin K11 and not K48, was also reported to be the chain topology relevant for PBI extrusion (Pomerantz et al., 2012). This last study further demonstrated that ubiquitin K11 chain mediates not only PBI extrusion but also appropriate chromosome segregation. This finding agrees with previous reports that K11 chains mediate degradation of the APC/C, cyclin B1 and securin (Kirkpatrick et al., 2006).

Unlike the large body of information accumulated regarding the ubiquitination enzymes, very little is known about those enzymes that facilitate, deubiquitinating enzymes (DUBs). Nevertheless, their involvement in regulation of the meiotic cell cycle is suggested by inhibition of carboxy-terminal hydrolyse (UCH)-family DUBs, which resulted in perturbed PBI extrusion and abnormal MII spindle formation; these oocyte could not be fertilized (Mtango et al., 2012a,b).

The family of E2 in human contains around 40 members (Huang et al., 2007), with several of which shown to have roles in mitosis (Jin et al., 2008). Nevertheless, it is only recently that E2s were identified in meiosis. In particular, the E2 family member, E2C and E2S were shown to be essential for spindle formation and their depletion inhibited PBI extrusion. Rescuing this phenotype was achieved upon expressing E2C, but not E2T, suggesting E2C indispensability (Ben-Eliezer et al., 2015). The mechanism by which these two E2s mediate the formation PB1 was suggested by an earlier study (Reddy et al., 2007) demonstrating that their depletion prevented the APC/C binding to its coactivator CDK1 as well as the dissociation of Cdc20 from Mad2 and BubR1. Supporting this notion, high levels of E2C circumvent spindle assembly checkpoint (SAC) inhibition of the APC/C, leading to premature cytokinesis (Ben-Eliezer et al., 2015). E2D3 depletion also led to inhibition of PBI extrusion in oocytes (Ben-Eliezer et al., 2015). This E2 interacts with APC/C and ubiquitinates securin and cyclin B1 (King et al., 1995). It is possible that E2D3 replaces, at least in part E2C in initiating ubiquitin chain formation on those proteins. As mentioned above, the K11 is the major ubiquitin chain in PBI extrusion (Pomerantz et al., 2012). Interestingly, U2C, U2S and U2D3 promote K11 chains on APC/C substrates (Kirkpatrick et al., 2006; Dynek et al., 2010).

Cytokinesis

Cytokinesis is a complex process, which involves five protein clusters essential for the conclusion of the physical split of the oocyte and the PBI (Glotzer, 2005). The initial set of proteins includes the MKLP1-Cyk4 complex (centralspindlin complex) together with the Aurora B-incenp-survivin complex. Depletion of INCENP or inhibition of Aurora kinases B and C activates the APC/C complex before chromosomes have properly arranged on the spindle, arresting the oocytes at MI, thus preventing cytokinesis and PBI extrusion (Sharif et al., 2010). On the other hand, overexpression of Aurora B brings about APC/C inactivation and stabilizes securin; this phenotype is completely suppressed by INCENP depletion (Sharif et al., 2010). The second set of proteins belongs to the RhoA pathway including the ECT2 (RhoGEF) and a RhoGAP. This set of proteins activates the third class of proteins, the myosin II, that are the motor of the contractile ring, its regulators and the F-actin filaments (Jordan and Karess, 1997). Incubation of oocytes in the presence of the microfilament inhibitor cytochalasin D prevents cytokinesis, blocking PBI formation (Verlhac et al., 2000; Kubiak, 1991). The interaction of myosin II with actin and the formation of the actomyosin complex at anaphase are regulated by the fourth class of proteins including the formin2-profilin machinery. This protein complex organizes actin filaments that are essential for the contractile ring assembly (Evangelista et al., 2002). The last set of proteins responsible for the completion of cytokinesis involves the membrane fusion machinery that bridges the space remaining after full ingression of the contractile ring. This contraction of the actomyosin upon PBI extrusion takes place at telophase (Deng et al., 2009) and requires inactivation of CDK1 by

ECT2 (Elbaz et al., 2010). The actomyosin-ring contraction leads to protrusion of the cortex cap overlying the spindle. These events are regulated by the small GTPase, CDC42 and its downstream effector Arp2/3 complex, a major actin regulation complex, both detected in the cortex cap (Leblanc et al., 2011).

Ovulation

Ovulation is a multistep process stimulated by the preovulatory surge of the pituitary LH. The ovulatory response to LH includes oocyte maturation (discussed in details previously in this chapter) concomitant with cumulus expansion and its mucification (Dekel and Kraicer, 1978; Rimón-Dahari et al., 2016), culminating in the disintegration of the follicular wall and the release of a fertilizable oocyte (recently reviewed in Rimón-Dahari et al., 2016). Once the oocyte is released, the residual granulosa and thecal cells undergo reprogramming and differentiate into the corpus luteum (CL) in a process defined as luteinization. The major role of the CL is the production and secretion of progesterone that is crucial for pregnancy establishment and maintenance (Stocco et al., 2007). The complex series of events occurring at ovulation inevitably involves specific ovarian cell types, diverse signaling pathways and temporally controlled expression of specific genes (extensively reviewed in Richards, 2007).

Conclusion

Successful completion of the first meiotic division, characterized by the formation of PBI represents the accomplishment of a complex sequence of events, collectively responsible for proper chromosome segregation. Intensive investigation of the mechanisms, which underlie the fidelity of the separation of the nuclear DNA during meiosis, is of high significance for our understanding of aneuploidy. Aneuploidy and its associated severe genetic malformation, represents a compromised meiotic division in oocytes that is particularly common in women at advanced age. In the western society, in which women tend to postpone motherhood, generation of the relevant knowledge in this regard is of particular importance.

Maternal Programming in Oocytes

Kyeoung-Hwa Kim and Kyung-Ah Lee, CHA University, Bundang-gu, Korea

Introduction

Mammalian oocytes undergo a unique meiotic cell cycle that produces four daughter cells from one unevenly divided primary oocyte, and in three of these daughter cells, three polar bodies are degenerated, leaving a single large oocyte with most of the cytoplasm containing accumulated maternal RNAs and proteins. Consistent with follicular growth, oocytes in the follicle grow and mature into a large oocyte, and these processes are finely controlled by cell-to-cell communication between follicular cells and oocytes. This cell-to-cell communication is bi-directional and essential for the development and function of oocytes and granulosa cells (Su et al., 2009). Granulosa cells play a nurturing role in supporting oocyte development and a regulatory role in maintaining oocyte meiotic maturation and the global suppression of oocyte transcriptional activity. Additionally, oocytes are the control towers for the proliferation and transition of granulosa cells to cumulus cells in mice (Diaz et al., 2007a, b).

During oocyte growth and development, oocytes produce and store various types of RNAs and proteins in the cytoplasm. The factors stored in the oocyte cytoplasm are required for further processes, such as oocyte maturation, fertilization, and preimplantation embryo development, until new genes are expressed during the oocyte-to-embryo transition that occur after fertilization, namely, the maternal-to-zygote transition (MZT) (De La Fuente, 2006). The MZT is a major developmental transition that starts from fertilization until the stage where embryonic gene expression is concurrently initiated with the degradation of maternal factors from the oocyte stage (Fig. 1). MZT is essential for early embryo development since it organizes embryonic mitotic cell division with zygotic gene activation (ZGA). This unique pattern of dynamics in the transcriptome during the MZT, including the degradation of maternal mRNAs and new transcription of zygotic genes, is the product of maternal programming in oocytes. Both the degradation of maternal mRNAs and new transcription of zygotic genes are prerequisites for the normal development of early stage embryos (De La Fuente and Eppig, 2001; Jukam et al., 2017).

Category of Maternal RNAs

Full-grown mouse oocytes are transcriptionally quiescent, and the loss of the maternal mRNAs initiates when oocytes undergo maturation (Svoboda et al., 2015). This transcriptional quiescence in full-grown oocytes is maintained by the poly(C)-binding protein PCBP1 (Xia et al., 2012). However, while this transition is transcriptionally quiescent, maternal mRNAs are stable with a high turnover rate (Puschendorf et al., 2006). These dormant maternal mRNAs are considered a ready-made-form for use whenever certain developmental necessities arise. Although the functions of many genes have been revealed, the functions of many more genes remain unknown.

Based on studies of the functions of maternal mRNAs using loss-of-function methods, i.e., RNA interference (RNAi), these molecules can be characterized into two groups. The biochemical and molecular changes and the phenotypic changes of the oocytes after RNAi are compared to the in vitro maturation and in vitro fertilization of the control oocytes. One group includes maternal

Fig. 1 Maternal-to-zygotic transition. Maternal mRNAs synthesized and stored during oogenesis serve as the maternal contribution supporting oocyte maturation, fertilization, and early embryogenesis. However, accumulated maternal mRNAs undergo general decay after meiotic resumption (red line), followed by ZGA to switch the developmental control from maternal mRNAs to de novo transcripts expressed from the zygotic genome (green line). This transition is referred to as the maternal-to-zygotic transition. Indeed, upon fertilization, the condensed sperm nucleus undergoes chromatin remodeling in which maternally derived histones replace a majority of sperm protamines, resulting in the decondensation of sperm chromatin and the formation of PN.

mRNAs for which the loss-of-function of that specific gene results in the MI-arrest of oocyte maturation (Fig. 2B), while the other group includes maternal mRNAs for which the loss-of-function results in the completion of meiotic maturation but without full competent cytoplasmic maturation (Fig. 2C). When Obox4 was knocked down in GV oocytes, Obox4-RNAi-treated oocytes could not complete nuclear maturation and showed the abnormal organization of spindles and chromosomes and incomplete cytokinesis. The genes affecting RNAi-induced MI arrest are Obox4, Bcl2l10, Txnip, Zap70, etc. (Lee et al., 2013). Interesting phenotypic changes observed after Txnip RNAi included immobilized cytoplasmic streaming of the oocytes (Video B in the online version at <https://doi.org/10.1016/B978-0-12-801238-3.64454-9>) (Lee et al., 2013).

The results of the RNAi of other groups of genes showed no changes in progressing nuclear maturation by showing polar body formation after RNAi, but developmental abnormalities were observed after fertilization and beyond. Fertilization without paternal chromosome decondensation and pronucleus (PN) formation was observed in Gas6 RNAi-treated oocytes (Kim et al., 2011). In the case of Sebox RNAi, MII formation and fertilization progressed but no further embryonic development was observed after the 2-cell stage (Kim et al., 2016). According to these phenotypic changes after RNAi, we categorized the genes into two groups and analyzed the second group of genes as new candidates for maternal effect genes (MEGs).

Maternal Effect Genes (MEGs) and Their Functions

As previously explained, the oocytes of vertebrates contain maternal factors, such as mRNAs and proteins, which are accumulated and stored during oogenesis. These maternal factors regulate oocyte growth and maturation, meiosis, fertilization and early embryogenesis, including the transition between meiotic and mitotic cell cycles, the removal of maternal detritus (mRNAs and proteins) and the robust activation of the embryonic genome, the so-called zygotic gene activation (ZGA). Early embryo development is heavily dependent on specific maternal factors of oocytes prior to ZGA, and these specific maternal factors, genes from the maternal genome, are referred to as MEGs. Currently, the lists and functions of MEGs have revealed that these genes are important for the regulation of normal embryo development, as the disruption of the expression of MEGs resulted in defective embryogenesis (Fig. 3).

MEGs were initially described in *Drosophila* 30 years ago, such as dorsal, bicoid and torso, while the first MEG in mammals was described in 2000 using traditional knockout techniques (Kim and Lee, 2014; Tong et al., 2000). Since then, different techniques have been used to identify MEGs. The first MEGs were identified in mice using traditional knockout techniques. However, the global deletion of several MEGs essential for embryogenesis using traditional knockout techniques results in embryonic lethality, preventing the investigation of the function of MEGs in postnatal and adult life, including fertility. The emergence of conditional knockout techniques using a tissue-specific Cre-loxP system has overcome the risks associated with traditional knockout techniques, such as embryonic lethality and complex phenotypes. However, the process to generate a mouse using traditional/conditional knockout or mutant techniques is slow and expensive. Fortunately, the specific knockdown of MEGs in oocytes is a more rapid technique with lower costs, and this technique has been used to identify a growing number of MEGs in mammalian species, such as mice, cows, and pigs (Kim and Lee, 2014). Currently, more than 60 MEGs with pivotal roles in normal embryonic development have been identified in mammals (Condic, 2016).

Chromatin Remodeling

The mammalian sperm nucleus contains tightly packed chromatin with protamines. In successful fertilization, by entering the ooplasm, the condensed chromatin in the sperm head undergoes rapid decondensation and becomes repacked with maternally derived histones. This process, known as paternal chromatin remodeling, is induced by specific maternal factors in oocytes. Thus, maternal factors process the male genome and the subsequent formation of the male PN, resulting in syngamy with female PN (Fig. 1). During MZT, the robust activation of embryonic gene expression also requires chromatin remodeling. Brwd1, Gas6, Npm2, Trim24 and Ube2a play essential roles in chromatin remodeling. We identified Gas6 as a MEG using RNAi. Following the microinjection of Gas6 dsRNA into the ooplasm of oocytes, disruption of Gas6 does not affect nuclear oocyte maturation but influences cytoplasmic maturation and chromatin remodeling, resulting in the failure of PN formation (Kim et al., 2011).

Degradation of Maternal mRNAs and Proteins

The MZT is a conserved developmental process during which the stored maternally derived products, i.e., maternal factors, are cleared (Fig. 1; red line), and the embryonic genome is robustly activated (Fig. 1; green line). Thus, the MZT requires both the degradation of maternal products and zygotic activation. In mice, the genome in the growing oocyte is transcriptionally and translationally active, and maternal proteins are stored in the ooplasm of the enlarging oocyte. Hence, maternal products are deposited in the ooplasm during folliculogenesis and oogenesis. In contrast, during meiotic maturation, prior to ovulation, the oocyte genome is translationally quiescent and the polyadenylated mRNAs are cleared. Subsequently, maternal proteins are degraded in early embryo development. However, the degradation of maternal mRNAs and proteins may be necessary for ZGA. Ago2, Atg5, Dicer1, Uchl1 and Zfp3612 are MEGs that play critical roles in maternal factor degradation. Taken together, these MEGs may be involved in autophagy, the ubiquitin-proteasome pathway and the miRNA/siRNA system.

Zygotic Gene Activation (ZGA)

During the MZT, maternal mRNAs and proteins are rapidly erased and new mRNAs and proteins encoded by the embryonic genome are synthesized. The robust activation of the embryonic genome, referred to as ZGA, has been observed in many mammalian embryos, including those of mouse, rat, pig, cow and human, indicating a biological imperative in early embryogenesis. ZGA occurs at the 2-cell stage in mice, the 4-cell stage in pigs, and the 8-cell stage in cows and humans (Fig. 3).

ZGA is essential for the MZT required for subsequent embryonic development, and some MEGs, including Bnc1, Nlrp5, Padi6, Sebox and Smarca4, may be involved in this process. The depletion of these MEGs leads to a reduction of de novo RNA transcription in zygote to 2-cell stage embryos. Upon transcription inhibition during this period, the embryos were primarily arrested at the 2-cell stage, commonly referred to as the 2-cell block. Therefore, ZGA must occur early during mammalian embryo development. In a previous study using RNAi, we identified Sebox and Lin28a as MEGs. Sebox is essential for oocyte cytoplasmic maturation and may prepare the oocyte for embryonic development through orchestrating the expression of other important MEGs and ZGA (Kim et al., 2016). Furthermore, Lin28a is a maternal effect gene expressed in oocyte cytoplasm that does not affect oocyte maturation or fertilization but regulates embryo development, particularly ZGA at the 2-cell stage (Kim et al., 2016).

Genomic Imprinting

Upon fertilization, the oocyte and sperm genomes require epigenetic remodeling and the subsequent formation of a totipotent PN embryo. During this period, the paternal genome is actively demethylated, effectively erasing many spermatogenesis-derived methylation marks. In contrast, the maternal genome is passively demethylated prior to the first mitosis. In addition, the embryonic genome in the blastocyst is demethylated. Maternal factors also maintain DNA imprints during early embryo development. Moreover, dynamic histone modifications, and more specifically lysine methylation, may play important roles in the MZT. Maternal factors play pivotal roles in regulating the epigenetic modifications of the paternal and maternal genomes. Hence, the remodeling of both paternal and maternal chromatin induces the activation or silencing of various genes, ultimately resulting in cellular differentiation and normal offspring. The MEGs Ctf, Dnmt1, Dnmt3a, Dnmt3l and Dapp3 play vital roles in genomic imprinting.

Preimplantation Embryo Development

When the paternal nucleus fuses with the maternal nucleus to generate a zygote, the oocyte transits to embryo development, i.e., from the meiotic cell cycle to the mitotic cell cycle, a process fundamental to successful embryo development. In mice, the molecular components necessary for the reorganization of the division machinery, centrosome re-establishment and changes in spindle properties are produced. The disruption of MEGs in oocytes leads to the inhibition of preimplantation embryo development. Therefore, MEGs are essential for early embryogenesis. The MEGs Filia, Fmn2, Kpna6 and Tcl1 play essential roles in the regulation of the cell cycle and spindle organization.

Conclusion

In summary, oocytes restrain numerous maternal factors for growth and development and sequester resources for fertilization and preimplantation embryo development. Maternal programming is therefore important for normal reproduction and required for the preservation of the species. Studies on the molecular identities and functions, as well as the regulatory pathways for each maternal factor, are important and fascinating issues in reproductive biology.

In sexual reproduction, male and female gametes unite at fertilization, to generate a genetically unique individual, which combines both parental genomes. Instrumental to the success of embryo development is the haploidization of the parental genomes, so as to restore a diploid chromosome complement after gamete fusion. Meiosis is the process by which haploid gametes (i.e., in which each chromosome is present as a single copy) are generated from diploid parental germ cells (in which each chromosome is present as two copies). In addition, paternal and maternal homologous chromosomes exchange segments of DNA during meiosis, creating genetic diversity. In oocyte meiosis, haploidization is achieved via a succession of two asymmetric divisions, to produce a big egg, and two small daughter cells called polar bodies, in which supernumerary chromosomes are discarded. The fertilized egg will develop into an embryo, while polar bodies will eventually degenerate. In the great majority of mammalian species studied so far, including human, the first meiotic division is achieved shortly before ovulation. Hence, the ovulated egg has emitted the first polar body. Emission of the second polar body, a hallmark of meiosis completion, requires the egg to be fertilized.

In this article, we review the basic principles of polar body formation in the mammalian fertilized egg, and we introduce the concept of cortical polarization, a prerequisite for polar body formation. The results and concepts presented here are based essentially on studies realized with eggs from mammalian species, mostly mouse.

The Need for a Second Meiotic Division

Why does the egg need to execute a second meiotic division before the start of embryo development? The answer lies in the amount of genetic material—that is, the number of chromosomes—in the newly formed embryo (Roeder, 1997; Holt and Jones, 2009). When primordial germ cells, which are diploid cells, invade the embryonic gonads during fetal life, they initiate meiosis after a round of DNA replication (premeiotic S phase), such that every chromosome is made of two identical sister chromatids. Homologous chromosomes of maternal and paternal inheritance are next assembled by pair to form the so-called bivalents, or tetrads, a structure that will facilitate recombination events to create genetic diversity. During the first meiotic division (or meiosis-I), which takes place in the ovarian follicle, the oocyte assembles the meiotic spindle, a bipolar structure made of microtubules, which role is to separate the homologs, one set of which is discarded into the first polar body. This is referred to as the reductional division because the number of chromosomes in the egg is effectively divided by two. Meiosis-I is also referred to as maturation, because the oocyte becomes fertilizable. At the end of meiosis-I, both daughter cells (the egg, and the first polar body) have inherited only one homolog of each pair. Straight away, the chromosomes that have been retained in the egg assemble a new spindle, with chromosomes aligned at its center, primed for the second meiotic division. However, ovulated eggs remain arrested in the so-called metaphase-II stage until fertilization (or until death by apoptosis, if unfertilized). These metaphase-II chromosomes are made of two sister chromatids joined together at their centromeric region. This configuration is similar to chromosome alignment on the mitotic spindle in dividing somatic cells. Since the sperm brings one full set of paternal chromatids, the egg effectively contains three copies of each chromosome after sperm fusion. But this is a transient situation, as fertilization also triggers meiosis resumption in the egg, leading to maternal chromatid segregation (anaphase-II) and the emission of the second polar body in which one set of maternal chromatids is discarded (Fig. 1). Ultimately, the fertilized egg contains one single copy

Fig. 1 Emission of the second polar body in the fertilized egg. In most mammalian species, the ovulated egg is blocked at the metaphase-II stage of meiosis (1). Upon fertilization, meiosis resumes and maternal sister chromatids (blue ovals) are segregated by the anaphase-II spindle (2). The fertilizing sperm also brings a full complement of paternal chromatids (green oval). In the mouse, the spindle lies parallel to the egg cortex and must rotate on the side during anaphase-II to achieve polar body formation (3). Next, maternal and paternal chromatids decondense and become enclosed into the maternal and paternal pronuclei (blue and green circles), indicating the end of meiosis (4). PB1: first polar body; PB2: second polar body.

(one chromatid) of each maternal and paternal chromosome, thus restoring a diploid chromosome complement compatible with healthy embryo development. Failure to emit the second polar body would result in triploidy, a condition incompatible with normal embryo development, and a likely cause of spontaneous abortion (Zaragoza et al., 2000).

Polar Bodies: Small Daughter Cells Formed Through Asymmetric Division

The egg contains large amounts of organelles (such as the energy producing mitochondria), proteins, as well as coding and noncoding RNAs, that have accumulated during oocyte growth in the ovary. These maternal stores are vital for successive accomplishment of the first phase of embryo development—the so-called preimplantation development. Therefore, it is important that polar bodies, which inevitably incorporate cytoplasmic content, remain as small as possible, in order for the fertilized egg to retain maximal amount of these precious resources. Emission of the polar body can thus be seen as a paradigm of asymmetric cell division, where daughter cells differ strikingly in size. For instance, the human egg is a large cell with a diameter of about 100 μm , while polar bodies are in the range 15–20 μm . To achieve such asymmetry, the spindle apparatus must localize very close to the egg cortex. During meiosis I, the first meiotic spindle forms in the oocyte center, then migrates towards the cortex while homologous chromosomes are still held together. When the spindle reaches the cortex, homologs separate, and one set is discarded into the first polar body. Next, the metaphase-II spindle forms and remains close to the egg cortex for the duration of the metaphase-II arrest (Fig. 2). The metaphase-II spindle is therefore ideally positioned to produce a second asymmetric division when meiosis II resumes at fertilization. In the mouse egg, the long axis of the metaphase-II spindle lies parallel to the cortex, such that the spindle will have to rotate during anaphase-II in order for the second polar body to protrude (Fig. 1). In human eggs however, as in other mammalian species, the metaphase-II spindle displays a perpendicular orientation relative to the cortex (Coticchio et al., 2013), suggesting that polar body protrusion at fertilization occurs without the need for spindle reorientation.

The Role of Ca^{2+} Signaling in Polar Body Formation at Fertilization

There are fundamental differences in the mechanisms regulating polar body formation in mammalian meiosis-II, versus meiosis-I. This is exemplified in the fact that once oocyte maturation starts, it proceeds autonomously through the successive cell cycle stages, culminating with the emission of the first polar body. In contrast, formation of the second polar body requires the triggering of a signaling cascade that is specifically elicited at fertilization, otherwise the egg remains arrested at metaphase-II. It is well established that the fertilizing sperm triggers a series of Ca^{2+} oscillations (periodic increases in the concentration of Ca^{2+}) in the mammalian egg, with effect to induce anaphase-II, emission of the second polar body, and a number of other events collectively referred to as egg activation (Jones, 2005; Perry and Verlhac, 2008). The trigger for this Ca^{2+} signal is a sperm-specific phospholipase C that is introduced into the egg cytoplasm upon gamete fusion (Swann and Lai, 2016). It is however possible to artificially induce meiosis-II resumption without a fertilizing sperm, using specific culture conditions or molecules that will trigger a rise in Ca^{2+} in the egg. This strategy is sometimes used in the clinic to rescue in vitro fertilized eggs that have failed to activate (Vanden Meerschaut et al., 2014).

Polarization of the Egg's Cortex

Beside the asymmetric positioning of the meiotic spindle, another feature of the ovulated metaphase-II egg is the remarkable remodeling of the cortical area overlying the spindle, a phenomenon referred to as polarization (Fig. 2, left and middle panels).

Fig. 2 Egg polarization. Left panel: schematic of a mouse egg arrested at metaphase II, showing some of the typical polarization features. Middle panel: optical slice of a mouse metaphase-II egg obtained by confocal microscopy. The egg was fixed and permeabilized, and stained for metaphase chromosomes (blue), spindle microtubules (green) and actin filaments (F-actin, red). Note the polarized F-actin cap overlying the meiotic spindle. Scale bar is 10 μm . Right panel: the molecular cascade leading to actin polarization in the mouse egg.

This has been extensively described in the mouse egg, where polarization was first detected over 40 years ago, as an exclusion of cortical granules from the spindle area (Nicosia et al., 1977). These granules, which cover the rest of the egg cortex, are exocytosed at fertilization, and their content contributes to establishing a barrier to polyspermy via the modification of the zona pellucida. Simultaneously, it was noticed that microvilli, finger-like membrane processes that are important for sperm binding and fusion, were disassembled in the membrane area overlying the spindle, possibly to prevent sperm fusion in this region (Nicosia et al., 1977). It was later shown that the polarized cortex shows a dramatic enrichment in actin filaments—the so-called actin cap (Longo and Chen, 1985; Maro et al., 1986). Most interestingly, egg polarization is unambiguously associated with chromosomes being in close vicinity to the cortex, no matter the precise location of the chromosomes, while spindle microtubules are not required. This lead to the proposal that maternal chromosomes send a signal to remodel the nearby cortex from a distance, and that this cortical differentiation is not restricted to a predetermined site (Longo and Chen, 1985; Maro et al., 1986). A similar accumulation of actin filaments overlying metaphase chromosomes was reported in other mammalian species (porcine) as well as in amphibians (*Xenopus*) and marine invertebrates (ascidian). The existence of an actin-rich cortex in the vicinity of the spindle has also been suggested in human eggs (Coticchio et al., 2014). Since the first description of the actin cap, other proteins were found to be enriched in the polarized cortex, such as myosin-II and the so-called polarity proteins Par3 and Par6. Reciprocally, some proteins—such as those involved in microvilli formation and sperm binding—have been shown to be selectively excluded from the polarized cortex.

Molecular Insights into the Polarizing Signal Delivered by Chromosomes

While the molecular mechanisms of egg polarization are not fully understood, one particular signaling cascade has been investigated in more details: the formation of the cortical actin cap in the mouse egg (Fig. 2). A major breakthrough was the discovery that the signal emanating from chromosomes to remodel the cortex, is a gradient of activated Ran GTPase (Deng et al., 2007). At the molecular level, cytoplasmic Ran is loaded with GTP (RanGTP, the active form) by its specific guanine nucleotide exchange factor RCC1 which is bound to chromatin, such that egg chromosomes act as a source of freely diffusing RanGTP (Dumont et al., 2007). The intrinsic GTP hydrolyzing activity of Ran (presumably amplified by GTPase-activating proteins) means that RanGTP will turn into inactive RanGDP as it diffuses away from the chromosomes. The net result is a gradient of RanGTP, centered on the maternal chromosomes (Fig. 2). Further studies identified signaling intermediates activated downstream of RanGTP to polarize cortical actin, such as the actin nucleator Arp2/3, the GTPase Cdc42 and the Cdc42 effector N-WASP (Yi et al., 2011; Dehapiot et al., 2013). The signaling cascade as we know it is shown in Fig. 2 (right panel). Accordingly, inhibition of any one of these signaling intermediates, leads to a loss of actin polarity, even though chromosomes are close to the cortex (Deng et al., 2007; Yi et al., 2011; Dehapiot et al., 2013). Importantly, inhibition of this signaling pathway in eggs cultured in vitro, also results in a failure of polar body formation after egg activation (Dehapiot et al., 2013). The Ran/Cdc42/Actin pathway is therefore instrumental to successful polar body emission following egg activation. This pathway seems conserved in meiosis-I, as genetic ablation of Cdc42 in mouse oocytes resulted in a failure to polarize actin and to emit the first polar body, leading to maturation defects and female sterility (Wang et al., 2013). It is likely that additional signaling pathways contribute to achieving egg polarization, possibly also under the control of the RanGTP gradient.

Examination of actin filament distribution in fertilized eggs reveals that the second polar body is enriched in actin and other polarity proteins such as N-WASP, while these proteins are no longer enriched in the egg cortex (Fig. 3). Effectively, the polarized cortical region in the unfertilized egg delineates the contour of the polar body to be formed, and thus polarized proteins end up in the polar body. Because actin filaments can act as force generators, controlling cell shape and deformation, it is likely that the polarized actin cap facilitates membrane protrusion during polar body formation (Dehapiot et al., 2013). In addition, the thick actin layer may provide the polar body with a structural coherence, preventing its collapse during the protrusion process. As mentioned earlier, the mouse egg shows a peculiar configuration whereby the spindle lies parallel to the cortex during anaphase-II (Fig. 1). It was shown that the polarized cortex effectively split in two during anaphase-II, resulting in the formation of two polar body-like protrusions enriched in actin and polarized proteins (Dehapiot et al., 2013). These observations suggest that the molecular cascade elicited by Ran to polarize the cortex is conserved during anaphase-II, and drives the protrusion of the second polar body at fertilization.

New Advances from Live Imaging Studies

A classic approach in egg research utilizes immuno-labeling of proteins of interest, in eggs that have been fixed and permeabilized (as seen in Figs. 2 and 3). Though this technique has generated valuable data regarding the subcellular distribution and relative amount of a number of signaling proteins, it cannot provide conclusive informations on protein dynamics and cytoskeletal remodeling as they occur in the living cell. New achievements in live imaging techniques, associated with the design of dedicated fluorescent probes, have allowed for the monitoring of actin filament dynamics in living eggs. Remarkably, it was shown that actin filaments in the polarized cap flow continuously towards the egg interior, and generates cytoplasmic streaming that contributes to maintaining the cortical positioning of the metaphase-II spindle (Yi et al., 2011). Future studies based on a similar live imaging approach should provide new advances in our understanding of polar body formation after fertilization, and the exact roles of actin filaments.

Fig. 3 Polarity features in the second polar body. Images are optical slices of mouse eggs obtained by confocal microscopy. Eggs were fixed and permeabilized before staining. Upper panels: a metaphase-II egg showing the polarized accumulation of actin filaments (F-actin) and N-WASP in the cortex overlying the spindle. Lower panels: a fertilized mouse egg with the second polar body emitted (PB2). Note the accumulation of actin and N-WASP in the cortex of the polar body. Chromosomes are in blue.

The Reprogramming Power of the Oocyte

Keith E Latham, Michigan State University, East Lansing, MI, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Somatic cell nuclear transfer (SCNT) was first proposed as a way to assess genetic totipotency of somatic cells within the context of whether genetic material was lost as cells differentiate. Little thought was initially given to the oocyte role in this experiment. Subsequently, the remarkable power of oocytes to reprogram exogenous nuclei was dramatically demonstrated, first in amphibians, and later in mammals, during the production of cloned animals. Cloning has been used for decades thereafter to generate cloned animals, first from embryonic cells, and subsequently from adult somatic cells, with valuable application in basic research, agriculture production, transgenesis and biopharmaceutical production, endangered species preservation, and most recently in the production of novel genetically modified animals capitalizing on advancement in genome editing technologies.

Throughout all this rich history, the nature of ooplasmic factors that support genome reprogramming has remained elusive. Many studies in the cloning field enumerate the many deficiencies and technical barriers to cloning, and report methods for enhancing reprogramming and cloning success by treating donor cells before nuclear transfer or by treating cloned constructs after nuclear transfer. A more limited set of studies addresses ooplasmic factors in cloning, using a combination of genetic, proteomic, and transcriptomic approaches, often coupled to in vitro reprogramming systems to better understand the functions of certain molecules. These lines of study have increased our understanding of oocyte biology, the epigenetic mechanisms that help establish each new life, and how the power of the oocyte might be more efficiently harnessed to achieve desired outcomes. Understanding the nature of oocyte reprogramming capacity will require an appreciation for the unique biological processes that are driven by the ooplasm during normal development, the changes in the cellular abundances and activities of the relevant factors during oocyte maturation and embryo development, and the contributions of these ooplasmic changes to how the overall outcome is influenced by the source of donor cell nuclei as a substrate for ooplasmic actions. Much of this insight has yet to emerge, making this an exciting area of research.

In this article, the reprogramming power of the oocyte is considered both in terms of epigenetic changes that occur during normal development and their contributions to normal events (Fig. 1), and in terms of changes imposed on somatic cell genome following nuclear transfer, to what extent normal events are recapitulated or not recapitulated (Fig. 2), and the consequences for cloned embryo viability. The article also considers reprogramming related to meiotic processes, and reprogramming related to genome function. Both aspects of reprogramming are essential for viability.

Fig. 1 Summary of major epigenetic changes in mouse oocytes and fertilized embryos. Region in *yellow* highlight indicates the period during which reprogramming events related to meiosis and initial transcriptional programming of the embryonic genome to support development occur. GVBD, germinal vesicle breakdown.

Fig. 2 Summary of major events associated with nuclear transfer in mice. Region in *yellow* highlight corresponds to the highlighted region in **Fig. 1**. As indicated, recapitulation of the events during this period, related to both meiosis and gene transcription, is imperfect, with the result that cloned embryos are markedly dissimilar to normal embryos (as indicated by $\neq$).

Oocyte and Donor Cell Genome Reprogramming Related to Meiosis

The critical cellular organ for meiosis is the meiotic spindle. Chromatin plays a crucial role in spindle formation. Without chromatin spindles can form, but are highly disorganized. Chromatin in which histones H3 and H4 have undergone deacetylation allows binding of RCC1, which in turn initiates the formation of a gradient of *Ran*-GTP emanating from the chromosome and locally directing microtubule polymerization and chromosome attachment (Zierhut and Funabiki, 2015).

After SCNT, donor nuclei lose their nuclear envelopes, undergo chromatin condensation, and direct the formation of new spindles within an hour (Gao et al., 2004). In principle, recapitulating spindle formation following SCNT provides a novel way of studying oocyte meiosis. However, spindles that form after SCNT are defective. They fail to acquire many key proteins in the correct abundances typical of well-formed spindles, and can have abnormal morphologies (Miyara et al., 2006; Han et al., 2010). Chromosomes display gross deficiencies in congression and attachment to the spindle. These defects persist into the initial mitotic cleavage divisions, and cloned embryos display increased incidences of aneuploidy.

Interestingly, spindles that form after transfer of embryonic nuclei (ECNT) are more normal (Miyara et al., 2006), indicating some donor cell-dependent feature of chromatin affects the quality of the spindle that forms. A difference in overall histone H3–H4 acetylation state could account for this. Histone deacetylase complexes are important for maintaining pluripotency and developmental capacity, and for maintaining appropriate patterns of lineage-specific gene expression. These observations indicate that the ability to deacetylate histones may be lost in the oocyte by the mature MII stage, that there may be insufficient opportunity for deacetylation to occur before chromatin condensation, or both. Interestingly, the oocyte variant histone H1FOO assembles onto chromatin within just 5 min of nuclear transfer (Gao et al., 2004), indicating the chromatin remodeling process initiates very rapidly.

The relative timing of histone deacetylation and chromatin condensation may be disrupted with SCNT to mature MII stage ooplasm, in which co-presence of factors that may normally appear and act in a specific temporal sequence during oogenesis precludes the normal required sequence of events. Thus, while spindle formation after SCNT superficially appears to recapitulate oocyte meiotic spindle formation, and while the mature oocyte contains all the factors needed to drive this seeming recapitulation, the key ingredient of temporal specificity of action of some of these factors appears lacking.

Oocyte Reprogramming of Parental Genomes After Fertilization

Following SCNT, there is extensive transcriptional reprogramming of the donor nucleus, so that differentiated genomes cease to express many somatic cell marker genes, and begin expressing pluripotency markers and other genes appropriate to early embryonic stages. The transcriptional reprogramming power of the oocyte reflects the capacity to reprogram gamete genomes during each life cycle. The sperm and egg genomes each directed the formation of highly specialized differentiated cell types. Accordingly, preparing the embryonic genome for embryogenesis requires reprogramming gamete chromatin to an embryonic state. This process

encompasses many global changes in DNA methylation and histone acetylation (**Fig. 1**). The maternal and paternal genomes undergo somewhat different transitions, particularly during the first two cell cycles after fertilization. For example, the paternal genome, but not the maternal genome, undergoes active DNA demethylation during the 1-cell stage within 4 h of fertilization, and then passive demethylation during cleavage. The paternal pronucleus lacks lysine 9 di- and tri-methylated histone H3, but contains histone H3 mono-methylated at lysine 9 and lysine 27, and trimethyl-histone-K27 appears after DNA replication. The maternal pronucleus contains lysine 9 di- and tri-methylated histone H3. With active demethylation of the paternal pronucleus comes increased 5-hydroxymethylcytosine content generated by TET3, and inhibited by DPPA3 in the maternal pronucleus (**Szabo and Pfeifer, 2012**). Reprogramming of the embryonic genome and onset of gene transcription are coupled to DNA replication. Progression through the first S phase after fertilization establishes the ability to perform gene transcription, whereas progression through the second S phase establishes the need for transcriptional enhancers (**Latham, 1999**). Ooplasmic changes accompany these transitions. Early 1-cell stage cytoplasm is transcriptionally repressive and can exert an extended repressive effect on gene expression after nuclear transfer (**Latham, 1999**). Such transitions may contribute to differences in cloning outcome observed by varying the donor and recipient stages. Extensive changes in histone acetylation around the time of transcriptional activation, also dependent on DNA replication, have been described (**Latham, 1999**). The oocyte-expressed SIN3A histone deacetylation complex is required for transcriptional programming of the early embryo. Collectively, these observations demonstrate that the oocyte is endowed with a wide range of factors that modify histone acetylation and methylation and DNA methylation during early cleavage divisions.

Ooplasmic Factors Participating in Exogenous Nuclear Reprogramming

Following nuclear transfer to MII stage oocytes, donor cell nuclear envelopes break down, chromosomes condense, a new spindle forms, and chromosomes try to assemble onto the spindle. Despite the many defects observed, this sequence of events indicates that many of the processes leading to the progression of oocytes to MII stage are recapitulated. As such, it is likely that hundreds of proteins participate in these processes, and thus can be considered as participating in the overall reprogramming process. Thereafter, gene expression must be reprogrammed to an embryonic state; the efficiency of that process affects cloned embryo characteristics and viability (**Fig. 2**). Recent studies provide insight into some of the specific proteins that are likely involved.

Spindle Assembly Factors

The oocyte possesses the necessary factors required for chromatin condensation, and for subsequent spindle assembly. Spindle assembly is linked mechanistically to chromosome condensation. During normal oogenesis, chromosomes undergo histone deacetylation and histone H1 becomes replaced with the oocyte specific variant H1FOO (**De La Fuente, 2014**). Histone deacetylation allows binding of spindle assembly factors such as RCC1, RBBP4, and RBBP7, which allows the formation of a Ran-GTP gradient emanating from the condensed chromosomes, to catalyze microtubule polymerization and spindle assembly (**Zierhut and Funabiki, 2015**). Interestingly, the Ran-GTP gradient is required for formation of the MII spindle, but may be dispensable for forming the MI spindle (**Zierhut and Funabiki, 2015**). Thus, some of the factors that normally participate in progression to first meiotic metaphase may be diminished in abundance from the MII stage oocyte when SCNT is performed, possibly accounting for the many spindle defects observed after SCNT.

Cytoskeleton Components

In a recent genetic screen using recombinant inbred mice to identify genetic loci associated with the ability of SCNT embryos to progress through cleavage, two cytoskeletal scaffold proteins emerged as the strongest genetic candidates for factors affecting early clone development (**Cheng et al., 2013**). These factors may normally control the partitioning of transcription regulators between nuclear and cytoplasmic compartments. This partitioning may be highly regulated to ensure the correct sequence of reprogramming events in the early embryo. However, because the initial chromatin state of the donor genome is very different from gamete genomes following pronucleus formation, the interactions of these cytoskeletal scaffold proteins with factors that modify chromatin may not allow the normal sequence of reprogramming events to occur, leading to partial, or even chaotic, chromatin remodeling. Additional nuclear roles for these proteins have not been examined.

Actin exists in the nucleus, where it may organize nuclear components, regulate chromatin architecture, bind and regulate availability of nuclear transcription factors to participate in transcription, and regulate RNA polymerase II complex function. A major class of chromatin modifying proteins, the SMARC (SWI/SNF-related matrix-associated, actin-dependent regulator of chromatin) family of chromatin regulators, interacts with actin. Studies in *Xenopus* oocytes revealed that the Wave1 protein, which participates in actin filament organization, is involved in reprogramming (**Miyamoto et al., 2013**). Wave1 binds to transcription factors in the nucleus and regulates RNA pol II-dependent transcription. Nuclear actin polymerization regulates expression of the pluripotency factor Oct4/Pou5f1.

Intermediate filaments may also contribute to reprogramming. Vimentin is detected in oocytes and associates with condensing chromatin after SCNT; inhibiting its function negatively affects development of cloned embryos, but not parthenogenetic or fertilized control embryos (**Kong et al., 2014**).

Chromatin, Epigenetic, and Transcriptional Regulators

Oocytes are endowed with a rich supply of specialized histone variants, as well as factors that modify histones. Together, these proteins play significant roles in reprogramming genomes. Oocytes contain a unique form of linker histone H1, denoted H1FOO, which binds chromatin more tightly than somatic H1, and rapidly assembles onto chromatin after SCNT (Gao et al., 2004). Oocyte-expressed histone H3.3 is required for reprogramming, and cannot be substituted by donor cell expressed H3.3 (Wen et al., 2014). Two variants of histone H2, previously denoted as testis specific (TH2A and TH2B) are also expressed in oocytes, and can enhance induced pluripotency in fibroblasts (Huynh et al., 2016). Another oocyte factor, arginine methyltransferase 7 (PRMT7), which methylates H2A, H4, and other chromatin proteins (Miranda et al., 2004), also enhances induced pluripotency (Wang et al., 2016). Histone demethylases are also expressed maternally (Page-Lariviere and Sirard, 2014). Oocytes also contain multiple histone deacetylases, including HDAC1, HDAC2, HDAC3, and other chromatin modifying complexes that interact with HDACs activities, such as SIN3A and nucleoplasmin 2, as well as histone chaperone ASF1, which participate in reprogramming. Additional chromatin regulators are involved in DNA cytosine demethylation, such as DNA methylcytosine dioxygenase TET3, an activity that is inhibited in the maternal genome by the oocyte expressed developmental pluripotency associated protein DPPA3/PGC7/STELLA (Szabo and Pfeifer, 2012), contributing to active demethylation preferentially in the paternal pronucleus. Cullin-ring finger ligase-4, its linker protein DBB1, and substrate adaptor VPRBP/DCAF1 activate TET methylcytosine dioxygenases. Other transcription factors that contribute to oocyte reprogramming function include the transcriptional repressor RE1 silencing transcription factor (REST) (Kong et al., 2016), and oocyte-expressed Gli-like transcription factor GLIS1, which is required for cleavage development and enhances induced pluripotency (Maekawa et al., 2011).

While the oocyte possesses this diverse range of activities, reprogramming with SCNT is limited, and treating either donor cells or SCNT constructs with epigenetic drugs has proven beneficial. These include HDAC inhibitors such as trichostatin A, Scriptaid, valproic acid, oxamflatin, and others. However, excessive treatment with these epigenetic drugs can be detrimental, possibly due to non-specific gene deregulation, loss of imprinting, or loss of other key functional chromatin features. Increased histone acetylation may re-activate some genes contributing to early embryogenesis, but may also inhibit correct chromatin condensation and segregation, as discussed above. Donor cells can also be treated with protamines to enhance cloning (Czernik et al., 2016).

Telomerase and Resetting Replicative Potential

Production of cloned animals, and especially serial cloning through multiple generations or production of clones from aged animals or senescent cells, indicate that the ooplasm has the ability to reset replicative potential, and elongation of telomeres in cloned animals has been reported. This capacity interacts with donor cell characteristics, as both cell type and species affect telomere lengthening.

Mitochondrial and Metabolic Factors

A key component of oocytes is the mitochondrial population, which normally are exclusively matrilineally transmitted. SCNT can create mitochondrial heteroplasmy, although this appears somewhat variable, and subject to complex interactions that differ, as seen by variations in outcomes with different inter-species SCNT donor-recipient combinations. Nuclear reprogramming is an ATP-dependent, energy-intensive process. Metabolic disturbances have been reported in SCNT embryos, and it has been suggested that this negatively affects protein synthesis. The metabolic disturbances may reflect a combination of stress-induced responses and delayed reprogramming affecting embryonic physiology. Mitochondria in the oocyte and early embryo are electron dense with few transverse cristae indicative of reduced ATP-production potential, and become less dense, elongate, and develop transverse cristae during preimplantation development. The initial mitochondrial state may limit ATP production and limit reprogramming capacity. Compatibility between donor nucleus and oocyte mitochondria, and ability of the ooplasm to direct correct transcriptional regulation of mitochondrial genes are likely key factors in defining oocyte reprogramming potential.

Immediate Versus Later Reprogramming Events

Studies of SCNT mouse embryos revealed persistence of somatic cell-like features well into cleavage. Cloned embryos display a preference for somatic cell culture medium over embryo culture medium formulations, a preference for glucose containing media, and a preference for atmospheric oxygen concentration during culture (Latham, 2005). Additionally, cDNA microarray studies revealed hundreds of mis-regulated genes at the two-cell stage, including aberrant expression of transcription factors, which may direct aberrant transcription in a hierarchical manner, accounting for the large number of aberrantly regulated genes (Vassena et al., 2007). At later stages, cloned embryos display aberrant regulation of protein localization, and aberrant gene expression continues (Latham, 2014). Some transcription factors remain associated with the donor genomes after SCNT, and somatic cell-expressed genes continue to be expressed. These observations indicate that reprogramming is slow and likely continues throughout cleavage stages. This likely creates difficulties for providing cloned embryos with optimized culture environments, as their cellular and molecular characteristics would continue to evolve during cleavage development. Treatment of donor cells with epigenetic drugs or chromatin modifying proteins may provide a head start on reprogramming, which could improve outcome.

One study found that inhibiting DNA replication after nuclear transfer inhibited reprogramming and activation of pluripotency markers (Wang et al., 2014). This suggests that, just as DNA replication is required for embryonic genome reprogramming, so too it

contributes to reprogramming during cloning. This is also consistent with persistence of somatic cell characteristics during cleavage, indicating that reprogramming is a slow process that is facilitated by passage through embryonic cell cycles and associated rounds of DNA replication.

Species differences may exist in the pace of reprogramming. One study reported more rapid reprogramming with nuclear transfer to mitotically arrested zygotes in mouse as compared to human (Egli et al., 2011). This difference may reflect different kinetics of regulating ooplasm components following fertilization.

Relationship Between Oocyte Reprogramming Factors and Reprogramming Factors Used to Induce Pluripotency

The study of oocyte reprogramming factors has expanded in recent years through new initiatives to discover factors that can enhance induced pluripotency in cultured somatic cells. For example, oocyte-expressed histone variants, nucleoplasmin, and GLIS1, activation-induced cytidine deaminase, and geminin can enhance cellular reprogramming to make induced pluripotent stem cells (iPSCs) (Huynh et al., 2016; Maekawa et al., 2011). Oocyte expressed PRMT7 can substitute for SOX2 in the iPS protocol (Wang et al., 2016). Transcriptome comparisons between oocytes of different species have led to “candidate oocyte reprogramming factors” that are being tested for use in cellular reprogramming. Oocyte germinal vesicle extracts and oocyte extracts from different species have been considered in cellular reprogramming (Tokmakov et al., 2016). Genes elevated in expression in iPSCs relative to embryonic stem cells have been compared to oocyte transcriptomes for further selection of candidates. Reciprocally, factors used in making iPSCs have been used to facilitate reprogramming with SCNT. The discovery of different combinations of chromatin modifiers and other factors that can be used in combination to convert somatic cells in culture to pluripotency indicates that many pathways to pluripotency may exist, and that extreme overexpression of exogenous factors can overwhelm prior programming by transforming chromatin states at pluripotency-related loci. Discovering which of these pathways also operate during gametogenesis, which do not, and what are the common downstream mechanisms leading to pluripotency should reveal much new knowledge about how gametogenesis generates genomes that can direct the formation of a new individual. In addition, discovering how the oocyte components (cytoplasmic mRNAs, proteins) interact with the two gamete genomes to unlock the gametic programming should prove fascinating.

Conclusions

The oocyte is truly a remarkable cell, being endowed with the ability to vastly restructure chromatin, both in preparation for meiosis, and to generate one of two gamete genomes that must unite to form a new life. The oocyte also contains factors that interact with the sperm-derived genome to ready it for function, as well as factors that maintain and modify epigenetic information related to genomic imprinting, and factors that prepare the embryonic genome for transcription and enable transcription to be properly regulated. No other cell type possesses this capacity. The identification of factors that contribute to reprogramming during cloning by nuclear transfer, combined with identification of factors that enable induced pluripotency in vitro have shed important new light on the nature of ooplasm reprogramming factors. But the factors so far identified are comparatively few in number, and most are well-known for chromatin remodeling and transcriptional control in other contexts. Along with the identification of these factors has come the realization that the oocyte must contain many such factors, and that numerous factors must work in combination to accomplish the overall goal of reprogramming the oocyte genome for meiosis, and reprogramming pronuclei and the embryonic genome during early cleavage to support embryogenesis. Many of the reprogramming factors in the oocyte likely work in complementary pairs, which modify the oocyte and pronuclear genomes, and then reverse those modifications at the appropriate stages. This suggests that the activities of these factors must be coordinated with and regulated by signaling pathways within the oocyte that respond to exogenous stimuli as well as endogenous cues. This further implies that the oocyte will be sensitive to external insults, but that redundancies in functions and partitioning of functions between multiple factors may provide resistance to sustain overall oocyte quality even in the face of adverse environmental conditions. A better understanding of those functional redundancies and partitioning could provide new approaches to enhance oocyte quality for a range of purposes, as well as methods to enhance success of cloning and creation of induced pluripotent stem cells in vitro.

Using oocyte factors to enhance induction of pluripotency, using iPS factor to enhance cloning outcome, or treating donor cells or clone constructs with epigenetic drugs all show some success and some promise. But all these approaches carry risk of incorrect reprogramming, with unintended effects on some target genes potentially negating favorable effects at other genes, as well as risk of disrupting essential imprinting information and other epigenetic information that guides early development and even determines adult phenotype. Additional attention to reprogramming chromatin to a state that can work with oocyte factors to enhance chromosome congression and spindle quality could also be helpful.

Regulation of the Oocyte Epigenome During Prophase I Arrest

Meiosis

Meiosis is a process of cell division where a eukaryotic diploid cell originates one or more haploid cells, being essential for gamete production and maintenance of ploidy after egg fertilization. Meiosis is similarly important for generating genetic diversity through chromosome recombination and segregation. Not surprisingly, meiotic defects often lead to sterility and developmental defects (Ohkura, 2015).

Diploid cells ($2n$) contain two sets of chromosomes, being one set usually from the mother and another set from the father. A homologous chromosome set corresponds to a pair of chromosomes in a diploid cell. After each round of DNA replication during S-phase, a diploid cell contains two copies of each chromosome ($4n$), forming sister chromatids that are held together by the cohesin complex. As a diploid cell enters meiosis, pairs of sister chromatids from the homologous chromosomes are matched together and genetic material is exchanged by crossing over during prophase of meiosis I (prophase I). After synapsis formation and initiation of crossing over during prophase I, the homologous chromosomes are held together by chiasmata during metaphase I and until the onset of anaphase I, when they are resolved and the homologous chromosomes separated. Sister chromatids for each homologous chromosome are subsequently separated in meiosis II in a process similar to mitosis (Ohkura, 2015).

Gametogenesis

Gametogenesis is the process by which sperm and eggs are produced from the germ cells in the testes and ovaries, respectively. Although males and females have meiosis and differentiation as the central points of gamete formation, they differ in the timing of differentiation in relation to meiosis (Von Stetina and Orr-Weaver, 2011). Whereas spermatogenesis is a continuous process where male germ cells undergo meiosis and then differentiate into the respective spermatozoa (Sharma and Agarwal, 2011), differentiation of female germ cells takes place during meiosis, being its progression frequently arrested during oocyte maturation (Von Stetina and Orr-Weaver, 2011). The meiotic arrest at the diplotene stage of prophase I is a highly conserved feature of female meiosis across all studied metazoans (Fig. 1A–C), being usually coincident with significant oocyte growth and maturation (Arur, 2017; Greenstein, 2005).

Danio Rerio and *Xenopus Laevis* Oogenesis

Oocytes of most animals are large single cells that contain all materials necessary for development of the embryo until the new individual can begin feeding. In the case of non-mammal vertebrates, like zebrafish (*Danio rerio*) or clawed frog (*Xenopus laevis*), their oocytes are remarkably large and rich in storage proteins. In *Danio rerio* the primordial germ cells (PGCs) differentiate into oogonia, which subsequently form the primary oocytes at the beginning of meiosis. The primary oocyte then becomes arrested at the diplotene stage of prophase I (Lubzens et al., 2010). During this arrest there is a massive growth of the oocyte with an accumulation of a large stockpile of storage proteins (vitellogenesis) needed for the development of the embryo after fertilization. Primary oocyte maturation then continues with germinal vesicle breakdown and completion of the first meiotic division. From the first meiotic division results the secondary oocyte and a very small polar body that degenerates. The oocyte maturation process is followed by ovulation, and as in most vertebrates, the secondary oocyte becomes arrested again during the second meiotic division in metaphase (metaphase II) until fertilization (Gilbert, 2000). *Xenopus laevis* oogenesis is similar to *Danio rerio*, as it starts in the embryo roughly 3 weeks after fertilization, as the PGCs begin differentiating to form primary oogonia, being cell growth considerably slow. Meiosis begins after the formation of the secondary oogonia and continues until an arrest at the diplotene stage of prophase I. During this arrest, vitellogenesis takes place and the oocytes grow considerably, with an accumulation of storage proteins. Oocyte meiotic progression then continuous, with chromosome condensation and germinal vesicle breakdown, until it enters meiosis II and becomes arrested again in metaphase II (Rasar and Hammes, 2006; Perry and Verlhac, 2008).

Mammalian Oogenesis

Vertebrate oocyte maturation is remarkably conserved with most differences resulting from adaptations to distinct reproductive strategies. Mammalian oocytes are significantly smaller than oocytes from non-mammal vertebrates as they rely on the mother to provide most of the nutrients required for embryonic development. Mammalian oocytes arrest at diplotene stage of prophase I and subsequently at metaphase II. Most of oocyte growth occurs during diplotene I arrest, where there is a significant change of the primary oocyte transcriptome after reactivation of the dormant primordial follicle and before it progresses into metaphase

I and terminates meiosis I (Ernst et al., 2017). The secondary oocyte then arrests in metaphase II and ovulates. Release of metaphase II arrest occurs after fertilization.

Human oogenesis, starts when the embryonic primordial germ cells begin to differentiate into oogonia between the 6th and 8th weeks of gestation (Pelosi et al., 2015; Kim, 2012). The number of oogonia increases dramatically by mitotic proliferation from approximately 600,000 during the 8th week of gestation up to approximately 7,000,000 by the 5th month. Although the oogonia are formed in large numbers most die by apoptosis, and only the ones that survive will differentiate into an oocyte between the 15th week and 7th month of gestation. Oocyte differentiation results from an asymmetric mitotic division of the oogonium that gives rise to the future primary oocyte and another oogonium. As the primary oocyte enters meiosis, it progresses through meiosis I until it becomes arrested for several years in a dormant state at the diplotene stage of prophase I (Kim, 2012; Pepin et al., 2007; Pan et al., 2012). Granulosa cells surround this primary oocyte to form a structure called primordial follicle and produce various growth factors and cytokines that are crucial for oocyte viability and maturation (Havelock et al., 2004; Ernst et al., 2017). With puberty, and until the onset of menopause, groups of primordial follicles are continuously reactivated for further oocyte maturation. Since primary oocyte maturation takes over a year until ovulation a healthy adult ovary contains a large number of oocytes at distinct stages of maturation. Similar to other non-mammals vertebrates, primary oocyte activation is associated with a burst of gene expression, a significant change of the oocyte transcriptome, and considerable growth and maturation (Pelosi et al., 2015; Ernst et al., 2017).

Mouse oogenesis is largely similar to humans, with the only major differences being the time of each phase. At first, few primordial germ cells can be identified, but they divide mitotically and 12 days *post coitum* the number increases to 2500–6000 cells and by day 16th there are several million germ cells. Similarly to humans, the majority of these cells degenerate, with the rest progressing into the first meiotic division and becoming arrested at diplotene stage of prophase I. Mouse gestation normally lasts 21 days, and similar to humans, the oocytes are arrested in prophase I after birth. Throughout the lifetime of the mouse the dormant primary oocytes are continuously activated but only a small subset of oocytes ovulate, with most degenerating during maturation. The first meiotic division is only completed prior to ovulation so the oocytes are meiotically arrested during growth, and the second meiotic division only occurs after fertilization (Wassarman, 2012).

Drosophila Oogenesis

Drosophila melanogaster oogenesis is divided into 14 developmentally distinct stages, and takes approximately a week to be completed (Bastock and St Johnston, 2008; Lake and Hawley, 2012). Similar to vertebrates, PGCs differentiate within the developing ovary into germ line stem cells (GSCs); which are functionally equivalent to the vertebrate oogonia. *Drosophila* oogenesis starts, again similarly to vertebrates, with an asymmetric division of GSCs that produce an anteriorly localized GSC and a posteriorly localized cystoblast that will ultimately differentiate into a mature oocyte (Bastock and St Johnston, 2008). The cystoblast undergoes four incomplete mitotic divisions to produce a 16 cell-cyst interconnected by actin-based ring canals and a cytoskeleton-rich structure named fusome. Although the two cells that have four intercellular bridges attempt to enter meiosis only one will remain in meiosis and become the oocyte (Bastock and St Johnston, 2008). The other 15 cells will become nurse cells that support oocyte growth and maturation by synthesizing and transporting maternal factors into the oocyte. *Drosophila* oocyte growth and maturation is therefore mostly supported not by the oocyte itself but by the closely associated nurse cells.

Similarly to vertebrates, *Drosophila* oogenesis has a prolonged meiotic arrest at the diplotene stage of prophase I that correlates with a rapid growth of the oocyte. Interestingly, the transcriptionally quiescent diplotene-arrested oocyte nucleus transiently reactivates gene expression just before it progresses into metaphase I (Flora et al., 2017; Navarro Costa et al., 2016). Although potentially important for meiosis and oocyte maturation the signal responsible for such reactivation of gene expression is still poorly understood.

Outstanding Problem: How Is Oocyte Gene Expression Correctly Reactivated After Dormancy?

The meiotic arrest at diplotene stage of prophase I and the significant change of the oocyte transcriptome during reactivation and growth are highly conserved but poorly understood features of oogenesis. How can a dormant human primary oocyte correctly

Fig. 1 The arrest at the diplotene stage of prophase I is a highly conserved feature of female meiosis and is frequently associated with a period of oocyte dormancy followed by a period of rapid growth. (A) In *Homo sapiens* (human), the developing primary oocyte arrests for several years in a dormant state, before reactivation after puberty. Reactivation of the dormant primordial follicle is associated with a dramatic change in the oocyte transcriptome and rapid growth. (B) In *Drosophila melanogaster* (fruit fly), the developing oocyte also arrests at the diplotene stage of prophase I, with its nucleus forming a highly condensed structure, known as the karyosome, and becoming transcriptionally quiescent. Such quiescence does not impair oocyte growth as it mostly relies in the supporting nurse cells. The transcriptionally quiescent oocyte transiently reactivates gene expression before it progresses into metaphase suggesting a role in meiotic progression. (C) In *Danio rerio* (zebrafish), the developing oocyte arrests at the diplotene stage of prophase I. During this meiotic arrest there is a massive growth of the oocyte. The establishment of lampbrush chromosomes structures supports the extremely high levels of gene expression needed for such rapid growth.

reactivate gene expression after decades of dormancy? And to what extent is this reactivation important for female gamete competence and fertility?

As maintenance of female fertility in humans relies in the viability and correct reactivation of the dormant primary oocytes, a better understanding of these processes is likely to be highly relevant not only for fertility but also for the timely onset of menopause.

Our working hypothesis is that the oocyte epigenome plays a crucial role in the correct reactivation of the quiescent primary oocytes and their ability to produce fully competent female gametes.

Meiotic Arrest at the Diplotene Stage of Prophase I

Meiotic prophase I is subdivided into five stages: leptotene, zygotene, pachytene, diplotene, and diakinesis. During the leptotene stage the chromatin arranges into long and thin strands and at zygotene stage the synapsis of homologous chromosomes takes place, facilitated by assembly of central elements of the synaptonemal complex. Pachytene is the stage where homologous recombination, including chromosomal crossover, takes place. Subsequently, the oocyte progresses into the diplotene stage where it frequently enters a prolonged resting phase (Snustad and Simmons, 2015).

The diplotene I arrest is often associated with dramatic rearrangements of the oocyte chromatin architecture. Different species have different strategies to assure the correct maturation of oocyte at this stage (Fig. 1A–C). *Xenopus laevis* and *Danio rerio* chromosomes greatly expand in size and develop symmetric loops forming what is known as lampbrush chromosomes (Fig. 1C). Each loop in these chromosomes represents high levels of transcriptional activity and each loop has a reproducible size and a characteristic pattern. Oocytes of *Xenopus laevis* and *Danio rerio* are much bigger than mammals, so it is crucial that RNA synthesis is enough to sustain oocyte growth. At the end of the diplotene I arrest these lampbrush chromosomes structures disappear, growth is mostly halted, and the oocyte progresses into metaphase I (Appels et al., 2012).

Oocytes from mammals are significantly smaller in size than their vertebrate counterparts, without detectable lampbrush chromosomes, as there is no need to accumulate such large stockpiles of storage proteins to sustain embryonic development after fertilization (Fig. 1A). Before birth, the primary oocytes enter meiotic diplotene I arrest, being surrounded by supporting granulosa cells and forming long-lived quiescent ovarian structures named primordial follicles (Pan et al., 2012). After puberty, activation of the primordial follicles is marked by a change of the supporting granulosa cells from a flat to a cuboid architecture, a major alteration of the oocyte transcriptome, and subsequent resumption of oocyte growth and maturation (Ernst et al., 2017).

Drosophila oocyte arrest at diplotene stage of prophase I is accompanied by condensation of the oocyte chromatin into a structure known as the karyosome and the establishment of transcriptional quiescence (Fig. 1B). Such quiescence does not impair oocyte maturation, as growth is mostly provided by the supporting nurse cells (Bastock and St Johnston, 2008; Lake and Hawley, 2012). Interestingly, and despite the role of the nurse cells, prophase I-arrested oocytes transiently reactivate gene expression approximately 36 hours after karyosome formation, and just before they progress into metaphase I (Navarro-Costa et al., 2016). This transient reactivation of transcription is associated with a global change in oocyte chromatin architecture suggesting a role in meiotic progression.

Epigenetic Regulation

Epigenetics are stable phenotypes that cannot be explained by changes in the DNA sequence. Epigenetic modifications such as DNA methylation and histone modifications play an important role in the regulation of chromatin structure, guaranteeing that gene expression is temporally and spatially appropriate, and that cell-type specific patterns of gene expression are robustly maintained during development (Li et al., 2007). The epigenome of the prophase I-arrested oocyte is surprisingly dynamic, presenting an assortment of euchromatic and heterochromatic markers that vary during oocyte quiescence and reactivation (Navarro-Costa et al., 2016; Kageyama et al., 2007).

Drosophila oocytes show a considerable variation of distinct histone modifications during prophase I-arrest. Although the functional significance of many of these modifications for meiosis and oocyte maturation are still poorly understood, regulation of histone H3 lysine 4 trimethylation (H3K4me3), an euchromatic marker, and histone H3 lysine 27 trimethylation (H3K27me3), a heterochromatic marker, have been reported to be rate-limiting for oocyte chromatin architecture, meiotic completion, and female fertility (Navarro-Costa et al., 2016). During transcriptional quiescence prophase I-arrested oocytes maintain H3K4me3 at low levels compared to H3K27me3, whereas reactivation of oocyte transcription correlates with a significant decrease in the levels of H3K27me3, without any detectable change in the levels of H3K4me3, suggesting that the balance between H3K4me3 and H3K27me3 epigenetically controls oocyte dormancy and reactivation (Navarro-Costa et al., 2016).

Mammalian oocytes also present an assortment of euchromatic and heterochromatic markers, and the levels of H3K4me3 are similarly important for meiotic progression and transcriptional reactivation, as the functional association between H3K4me3 and specific gene expression during meiosis has been established (Kageyama et al., 2007; Shi and Wu, 2009; De La Fuente, 2006). Moreover, and again similarly to *Drosophila*, it has been demonstrated that the levels of H3K4me3 and H3K27me3 are dynamic during oocyte development and maturation, and that the disruption of the balance between them can lead to incorrect meiosis progression (Xu et al., 2017; Pan et al., 2012). Methylation of histone H3 lysine 9 (H3K9) is a heterochromatin epigenetic mark associated with

transcriptional silencing. The levels of H3K9 methylation are dynamic during oocyte maturation (Tachibana et al., 2007), being H3K9 dimethylation regulated by the ESET/SETDB1 complex (Wang et al., 2017). Disruption of H3K9 methylation during prophase I leads to immature gamete formation, being meiosis similarly arrested at pachytene stage in males and females (Tachibana et al., 2007; Wang et al., 2017).

The dynamism of the oocyte epigenome has also been revealed by the patterns of histone acetylation. Fully grown oocytes and growing oocytes have distinct patterns of histone acetylation, being the levels of H3K9, Histone 3 lysine 18 (H3K18), Histone H4 lysine 5 (H4K5), and Histone H4 Lysine 12 (H4K12) acetylation higher in mature oocytes (Kageyama et al., 2007; Pan et al., 2012). Interestingly, the histone acetylation levels are higher in SN (surrounded nucleolus)-type oocytes, where chromosomes are highly condensed around the nucleolus and transcription silenced.

The phosphorylation of histones is also important for meiotic completion and progression, as phosphorylation of H2AThr119 by the *Drosophila* nucleosomal histone kinase-1 (NHK-1) is necessary for acetylation of histones H3 and H4, synaptonemal complex disassembly, and chromosome condensation during karyosome formation (Ivanovska et al., 2005; Lancaster et al., 2010).

Histone Demethylases

Drosophila KDM5 histone demethylase (dKDM5; also known as Lid) localizes to the transcription-start site (TSS) of actively transcribed genes and negatively regulates the levels of H3K4me3 (Lloret-Llinares et al., 2012). dKDM5 also has a demethylase-independent H3K4me3 recognition function that positively regulates gene expression (Li et al., 2010; Liu and Secombe, 2015). Such dual function of dKDM5 potentially explains why the expression of different subsets of genes is positively or negatively regulated after KDM5 depletion.

Drosophila oocytes transiently reactivate gene expression during late prophase I. Female germ-line depletion of dKDM5, leads to a significant increase in the levels of H3K4me3 and precocious transcriptional reactivation of the quiescent prophase I-arrested oocytes (Fig. 2), without any detectable change in the levels of H3K27me3 and histone H3 lysine 9 di-methylation (H3K9me2) (Navarro-Costa et al., 2016). Although the overhaul architecture and growth of the developing egg chamber is not impaired after dKDM5 depletion, its oocyte chromatin architecture is nevertheless highly abnormal, with a defective assembly of the synaptonemal complex, abnormal progression of meiosis I and II, and a significant reduction of oocyte-competence and female fertility (Navarro-Costa et al., 2016; Zhaunova et al., 2016). Importantly, the demethylase activity of KDM5 is required for correct transcriptional reactivation of the oocyte and meiotic progression (Navarro-Costa et al., 2016), suggesting a role of this histone demethylase in the regulation of the oocyte epigenome, and further supporting the hypothesis that correct reactivation of the dormant primary oocyte is epigenetically regulated.

Our working hypothesis is that regardless of distinct reproductive strategies the regulation of oocyte epigenome during prophase I is highly conserved across metazoans. Consistently, depletion of mouse KDM5b leads to secondary female infertility (Zou et al., 2014), whereas deletion of mouse Foxo3 is associated with precocious primary oocyte reactivation and secondary infertility in older females (Castrillon et al., 2003). Interestingly, *Drosophila* KDM5 interacts with Foxo and positively modulates its DNA binding ability (Liu et al., 2014), suggesting a functional crosstalk between these two proteins during oocyte reactivation (Fig. 2). Further confirming the role of distinct histone demethylases in oocytes reactivation and maturation, mouse Sall4 is required for primary oocyte maturation and resumption of meiosis by modulating the expression of KDM5b, KDM6a, and KDM6b that are responsible for maintaining the correct levels of H3K4me3 and H3K27me3 modifications (Xu et al., 2017).

Fig. 2 The epigenetic mechanisms responsible for the correct transcriptional reactivation of the dormant/quiescent primary oocyte are likely to be conserved across metazoans. A functional crosstalk between Foxo transcription factors (e.g., *Drosophila* Foxo, mouse Foxo3, and human Foxo1) and distinct histone demethylases (e.g., *Drosophila* KDM5, and mammalian KDM5b and KDM6a/b) may be regulating oocyte reactivation during the meiotic arrest at the diplotene stage of prophase I.

Final Considerations

Mouse Foxo3 is expressed in the nucleus of the dormant primary oocytes, being responsible for preserving their quiescence state (Castrillon et al., 2003). After puberty, primordial follicle reactivation relies in nutritional and other local factors that stimulate mTOR signaling in granulosa cells of the dormant primordial follicles, leading to the secretion of a ligand that binds the oocytes cell surface receptor Kit (Kim, 2012; Saatcioglu et al., 2016). This binding induces primary oocyte reactivation by promoting PI3K/AKT signaling and subsequent Foxo3 inactivation, as AKT-dependent phosphorylation of Foxo3 leads to its nuclear export and inactivation.

Although the signaling cascades responsible for primordial follicle reactivation are reasonably well established, it is still unclear how an oocyte can correctly reactivate gene expression after long-term dormancy. Reactivation of the primordial follicles after years, if not decades, of dormancy, correlates with a dramatic change in human oocyte transcriptome (Ernst et al., 2017). How is this possible? What are the genetic and epigenetic mechanisms capable of ensuring that the previously dormant oocyte still “remembers” what to do and how to give rise to a fully mature female gamete. We hypothesize that the oocyte epigenome is crucial for the success of such developmental transition, having histone demethylases (like KDM5) a central role in this process.

Oogenesis In Vitro

The Processes to Be Reconstituted In Vitro: Mice

Oogenesis is a unique sequence of differentiation originated from primordial germ cells (PGCs), the precursor of the germ cell lineage (Fig. 1). PGCs arise from the proximal epiblast in response to bone morphogenetic protein 4 (BMP4) secreted from the adjacent extraembryonic ectoderm and Wnt3 produced autonomously in the epiblast (Lawson et al., 1999; Ohinata et al., 2009). PGCs are located at a base of the allantois soon after the specification, translocate to the definitive endoderm and then start to migrate through the hindgut toward the gonad, which eventually becomes the ovary or testis. Upon entering the gonad, PGCs differentiate in a sex-dependent manner, i.e., they enter meiosis in females to become primary oocytes. In the mid-gestation stage, primary oocytes form a germline cyst, within which they are connected by intercellular bridges. At the perinatal stage, a majority (approximately 70%) of oocytes are eliminated by cell death accompanied with fragmentation of the germline cyst. The remaining oocytes form primordial follicles with the surrounding squamous pregranulosa cells (Fig. 1). The primordial follicles function as a pool of oocytes, ensuring longevity of the reproductive life in the female.

After puberty begins, some of the primordial follicles are periodically activated. The first morphological sign of follicular activation is that squamous granulosa cells surrounding the oocytes become cuboidal; these are called primary follicles. Then the granulosa cells proliferate and form at least two layers of granulosa cells surrounding the growing oocyte; these are called secondary follicles. From primordial follicles to secondary follicles, it appears that folliculogenesis progresses in a gonadotropin-independent manner, based on the evidence that FSH-signaling is dispensable for the formation of secondary follicles. As the oocytes approach full maturation, the follicle structure changes significantly in response to gonadotropins, mainly FSH. The most drastic change is formation of an antrum, by which the granulosa cell population is structurally separated into cumulus and mural granulosa cells. The former population is important for oocyte growth, developmental competence and fertilization, whereas the latter is important for ovulation and estradiol production with theca cells. The fully matured follicles undergo ovulation in response to the LH surge. The oocytes resume meiosis and arrest at meiotic metaphase II (MII), indicating that they are ready for fertilization (Fig. 1).

Reconstitution of PGC Specification In Vitro: Mice

To reconstitute oogenesis in vitro, every differentiation step should be precisely reproduced in culture. Obviously the first step is to reconstitute PGC specification. In the beginning of this century, several groups reported the production of PGC-like cells from mouse embryonic stem cells (ESCs) (Hubner et al., 2003; Toyooka et al., 2003; Geijsen et al., 2004). In principal, these reports showed that embryoid bodies spontaneously, or directionally to some extent, differentiated into PGC-like cells that expressed germ cell-specific markers. However, the results of these reports have not been rigorously compared to PGC specification in vivo, as the molecular mechanisms of the in vivo system were not sufficiently clear at that time. In addition, these reports did not test the functionality—i.e., whether the PGC-like cells are capable of differentiating to fertile eggs and sperm. Therefore, these reports were not sufficient to provide a robust reconstitution of PGCs in culture.

Along with the accumulating evidence showing how PGCs are specified from the epiblast in vivo, reconstitution of PGC specification in vitro has become increasingly possible. Of note, an ex vivo culture condition sufficient for the robust induction of PGCs from the epiblast was determined (Ohinata et al., 2009). This culture system employs a set of growth factors: BMP4, BMP8b, leukemia inhibitory factor (LIF), epidermal growth factor (EGF) and stem cell factor (SCF). Importantly, PGCs derived from the epiblast in this ex vivo culture system gave rise to functional sperm. Using similar culture conditions, PGC-like cells

Fig. 1 Schematic diagram of oogenesis to be reconstituted in vitro. Oogenesis is composed of a unique line of differentiation processes. There are several key events (boxed) that can be criteria for evaluation of the in vitro culture system.

were derived from mouse ESCs and induced pluripotent stem cells (iPSCs) (Fig. 2A). In this method, the ability to progress to PGCs in response to BMP4 is conferred to ESCs/iPSCs by culturing with basic fibroblast growth factor (bFGF) and activin A (Hayashi et al., 2011). Gene expression analysis revealed that the transition in vitro was quite similar to that from ICM to the epiblast. The conferred state was essential for PGC differentiation, as ESCs without the treatment could not differentiate into PGC-like cells. The gene expression dynamics during the PGC specification in culture well recapitulates that in vivo. Consistently, epigenetic reprogramming represented by a rapid reduction of di-methylation on histone H3 lysine 9 (H3K9me2) and a gradual increment of tri-methylation of histone H3 lysine 27 (H3K27me3) was observed in the PGC-like cells much as in PGCs in vivo.

Oocyte and Sperm Production From ESC/iPSC-Derived PGC-Like Cells by Transplantation

Whether the PGC-like cells derived from ESCs/iPSCs are capable of differentiating into functional sperm or oocytes is an important criterion to verify the culture system. Recently developed transplantation technologies allow us to test this capability. Transplantation of spermatogenic cells into recipient seminiferous tubules was established by Brinster's group (Brinster and Zimmermann, 1994). In rodents, donor spermatogenic cells give rise to functional mature sperm in the recipient testis. Interestingly, PGCs, which are still an immature type of germ cells, can be used as donor cells in the transplantation: PGCs transplanted into neonatal testes give rise to functional sperm. Consistent with the previous evidence, ESC/iPSC-derived PGC-like cells gave rise to functional sperm after transplantation into the neonatal testes; fertilized eggs with the sperm gave rise to pups (Fig. 2B). The pups appeared to be healthy, as they grew to fertile adult mice without any premature death or developmental delay.

Transplantation technologies for the female germ line are not as sophisticated as those for the male germ line, partially due to the anatomical features of the ovary. In contrast to spermatogenesis, which takes place in the tubular structure of the male reproductive organ, oogenesis proceeds in the follicles, which are structures tightly enclosed by granulosa cells and theca cells. The follicle structure is assembled at the perinatal stage and is not formed de novo after the birth. Therefore, for transplantation of the female germ line, PGCs or oocytes must be transferred with surrounding somatic cells/tissues. Experimentally, transferring either a piece of the ovarian tissue or aggregations composed of PGCs and surrounding somatic cells has been proven technically feasible for oocyte production from donor tissues/cells (Matoba and Ogura, 2011). Accordingly, to produce oocytes from ESC/iPSC-derived PGC-like cells, gonadal somatic cells of fetal ovaries were aggregated with the PGC-like cells and then transplanted into the recipient ovary (Fig. 2B) (Hayashi et al., 2012; Hayashi and Saitou, 2013). At 4 weeks after the transplantation, fully grown oocytes at the germinal

Fig. 2 Reconstitution of PGC specification in vitro. (A) PGCLCs are specified from ES cells (or iPS cells) via epiblast-like cells (EpiLCs). Cells cultured in the cytokines and for the number of days indicated are required for the reconstitution. In the present study, two reporter constructs, Blimp1-mVenus (BV) and stella-ECFP (SC), were used for monitoring PGCLC differentiation. BF: bright field. (B) When PGCLCs are transferred to the testis and ovary, they give rise to functional sperm and MII oocytes, respectively. Sexually matched ES cells (or iPS cells) are required for producing the gametes, e.g., female ES cells for oocyte production. In the case of oocyte production, somatic cells from the E12.5 female gonad are essential for supporting oogenesis in the transplant.

vesicle (GV) stage were collected from the transplanted ovaries. The GV oocytes were capable of resuming meiosis and reached the MII oocytes. At least some of these ES/iPSC-derived MII oocytes were fully potent, as they were fertilized with wild-type sperm and gave rise to pups that grew to fertile adult mice (Hayashi et al., 2012).

Reconstitution of Oogenesis In Vitro: Mice

It has been a long-standing challenge to establish optimal culture conditions under which fully potent eggs can be efficiently matured from immature oocytes, such as those in primordial follicles. In mice, the milestone work in this field was conducted by Obrien and Eppig. In their series of studies, fully functional oocytes were derived from neonatal ovaries in culture (Eppig and O'Brien, 1996). Partly in continuation of their efforts, Morohaku et al. established an organ culture system using fetal ovaries. Notably, the system produced functional egg production from mitotic PGCs in the fetal ovaries, thereby demonstrating the first successful completion of meiosis in a female germ line in culture (Morohaku et al., 2016). These systems provided useful strategies for determining culture conditions that produce fully potent eggs from pluripotent stem cells.

The key advances in the studies described above were mainly (1) the prevention of multiocyte follicle (MOF) formation and (2) the improvement of culture conditions for oocyte growth. In the organ culture of fetal ovaries, MOF, a follicle containing more than two oocytes, is frequently formed, which eventually disturbs oocyte growth in culture. Although the mechanism of MOF formation remains to be clarified, previous studies have suggested that steroid hormones, such as estrogen and progesterone, and their agonistic molecules such as bisphenol A (BPA) and diethylstilbestrol (DES) trigger MOF formation. There is an interesting coincidence between appropriate follicle assembly and reduction of the steroid hormone concentration in newborns upon delivery. Based on these observations, Morohaku et al. tested several estrogen inhibitors and found that ICI182780 was the most effective for preventing fetal gonads from forming MOFs in culture (Morohaku et al., 2016).

There are two ways to make oocytes grow to full-size, namely 2D or 3D culture (Fig. 3). In the 2D culture method, mural granulosa cells with theca cells are removed to directly supply nutrients to cumulus-oocyte complexes (COCs) from the medium. In contrast, the 3D culture method leaves the follicle structure intact like in vivo. Which method is optimal seems to depend on the species used. 2D culture is useful for mice, cows, and pigs, whereas 3D culture is useful for humans and other primates (see below for details). Theoretically, an advantage of 3D culture is that it can encapsulate follicular fluid with COCs, thereby preventing the diffusion of factor(s) in culture. It has been reported that polymer materials, such as polyvinyl pyrrolidone (PVP), improve oocyte growth in the 2D culture system, which may be attributable to prevention of the diffusion and the resulting promotion of the paracrine effect. Morohaku et al. removed the mural follicle wall by treatment with collagenase and used medium containing PVP at 2%, in which oocytes grew to fully grown germinal vesicle (GV) oocytes. The GV oocytes were then transferred to medium for oocyte maturation containing LH and EGF for stimulating maturation accompanied with meiotic resumption. The resultant MII

Fig. 3 Two different approaches to follicular growth in vitro. Schematic diagrams of the 3D and 2D culture are shown at the top. Note that the follicle structure is conserved in the 3D culture, whereas a part of the follicle structure is removed in the 2D culture. Representative images of mouse follicles cultured by each method are shown. Scale bars, 100 μ m.

oocytes from the culture were capable of fertilization and full-term development (Morohaku et al., 2016). Although the efficiency of pup production by this approach is not as high as that in the usual in vitro fertilization (IVF) using ovulated oocytes, this study demonstrates, for the first time, that mitotic PGCs can differentiate into functional oocytes in culture.

Generation of Eggs From Pluripotent Stem Cells In Vitro

Building on the advances in the organ culture of fetal ovaries, it has now become possible to generate functional eggs from pluripotent stem cells (Hikabe et al., 2016). This is accomplished as follows. PGCLCs are derived from ES/iPS cells and then aggregated with gonadal somatic cells. The gonadal somatic cells are collected from female embryos at embryonic day E12.5, and then endogenous PGCs are removed from the somatic cells by magnetic beads-conjugated anti-SSEA1 antibody. Aggregation of PGCLCs and gonadal somatic cells is done in a U-bottom 96-well plate, and then the aggregate, called the reconstituted ovary, is transferred onto a culture membrane coated with collagen. The subsequent culture system can be divided into three sections—in vitro differentiation (IVDi), in vitro growth (IVG) and in vitro maturation (IVM)—in which oogenesis proceeds to primary oocytes in the secondary follicle, fully grown GV oocytes and MII oocytes, respectively (Fig. 4). Each section requires culture media and supplements different from those used for organ culture of the fetal ovary. A higher number of oocytes were formed in IVDi culture under the combined condition: alphaMEM (aMEM) for the first 4 days, followed by StemPro34 for 17 days (Hayashi et al., 2017). Consistent with the organ culture of the fetal gonad, addition of ICI182780 to the IVDi medium prevented the formation of MOFs. At the end of the IVDi culture, the individual follicles must be isolated to prevent retardation of the oocyte growth (Fig. 4).

After the isolation of the follicles, as described in the method of the organ culture system, collagenase is also effective to promote the oocyte growth in ES/iPS-derived oocytes. In IVG culture, the granulosa cells surrounding oocytes start to proliferate and eventually lift up the COCs onto the culture membrane, which exhibits a morphology resembling that of antral follicles (Fig. 4). In some cases, recombinant BMP15 and GDF9 can be added to promote the proliferation of granulosa cells. In accordance with the proliferation, oocytes grew in the COC. At 11 days of IVG culture, the COCs are picked up and then transferred to IVM medium that induces resumption of meiosis in the oocytes. During IVM culture, the oocytes extrude the first polar body and become MII oocytes (Fig. 4).

Fig. 4 Reconstitution of oogenesis in vitro. The culture system that reconstitutes the entire process of oogenesis is composed of IVDi, IVG and IVM. PGCLCs aggregated with somatic cells from the E12.5 female gonads are used as a starting material. During culture, the key differentiation processes (boxed) are observed. In the top fluorescence images, oocytes are illuminated by SC. The middle images are from immunofluorescence analyses of SC (green) and DAPI (white). The bottom images show meiotic progression with dynamics of synaptonemal complex protein 3 (SYCP3).

Generation of Pups From ES/iPS-Derived Eggs

ES/iPSC-derived MII oocytes are capable of fertilization with wild-type sperm. Moreover, the fertilized eggs have sufficient potency to give rise to pups. Hikabe et al. demonstrated that, although the developmental rate is low (see below), eggs derived from multiple lines of ESCs, embryonic fibroblast (MEF)-derived iPSCs and tail-tip fibroblast (TTF)-derived iPSCs developed to pups. The pups were apparently healthy, as they grew to adulthood with a frequency comparable to that of wild-type mice and were fertile (Hikabe et al., 2016).

Efficiency of the Oogenesis In Vitro

A reconstituted ovary is composed of 5000 PGCLCs and 50,000 gonadal somatic cells freshly collected from E12.5 female embryos. It is possible to store gonadal somatic cells in liquid nitrogen. In this case, 75,000 frozen-thawed gonadal somatic cells are used for a reconstituted ovary. Hikabe et al. reported that 5000 PGCLCs gave rise to, on average, 237.3 primary oocytes, 55.1 fully grown GV oocytes and 15.9 MII oocytes in IVDi, IVG and IVM culture, respectively. Since 30–50 reconstituted ovaries were produced in one culture experiment, roughly 450–800 MII oocytes were available in the culture. In IVF using wild-type sperm freshly prepared from cauda epididymis, almost half of the MII oocytes were fertilized, and then almost 60% of the fertilized eggs became 2-cell embryos. By transferring to surrogate mothers, 3.5% of the 2-cell embryos became pups. Production of pups from ES cell-derived 2-cell embryos is 20-times less efficient than that from in vivo-derived 2-cell embryos (from IVF using superovulated MII oocytes and wild-type sperm), suggesting that some properties of the oocytes produced in culture were deficient (see Limitations of mouse egg production from ESCs/iPSCs).

Productivity of oocytes from iPSCs is similar to that from ESCs. For example, Hikabe et al. reported that 27.0 MII oocytes on average were obtained from 5000 PGCLCs derived from iPSCs. Despite the comparable productivity, the efficiency of pup production from the iPSC-derived 2-cell embryos was even lower than that from the ESC-derived 2-cell embryos: only 0.3%–0.9% of the iPSC-derived 2-cell embryos transferred gave rise to pups. At least in part, this may be due to the inferior quality of iPSC cells compared to ESCs, which is mainly caused by incomplete reprogramming in the somatic cells.

Limitations of Mouse Egg Production From ESCs/iPSCs

By the in vitro culture system, hundreds of mature oocytes can be obtained from ESCs/iPSCs. However, the developmental potency of the mature oocytes is partially compromised. This is due to frequent asynapsis of the homologous chromosomes, precocious resumption of meiosis and aneuploidy (Hikabe et al., 2016). Almost half of the primary oocytes in the reconstituted ovaries showed asynapsis, which could be identified by phosphorylation of histone H2AX (γ H2AX). This was due not only to the origin of the primary oocytes but also the suboptimal culture conditions, since the asynapsis rate increased even in primary oocytes in the organ culture of fetal ovaries. Further refinement of the basic culture conditions will be needed. The transcriptome analysis revealed that genes expressing immature oocytes, which should be down-regulated in MII oocytes, were still highly expressed in ESC-derived MII oocytes. This indicates that ESC-derived MII oocytes remain immature and precociously resume meiosis. It is generally thought that the follicular environment prevents the oocytes from resuming meiosis until they have sufficiently grown up. This indicates that the 2D culture system fails to reproduce the entire environment of the antral follicles. Although it is difficult to find a clear causal relationship to explain these abnormalities, aneuploidy is slightly increased: aneuploidy is observed in 22.2% of ESC-derived MII oocytes, whereas it is seen in only 2.4% of wild-type oocytes.

Embryonic development seems to also be compromised in ESC-derived embryos. The fertilization rates were not significantly different, but the rate of blastocyst formation of ESC-derived embryos was four times less than that of wild-type embryos. Even after transfer into the uterus there is a gradual loss of embryos, which may be caused by genetic and epigenetic abnormalities. Notably, all of the obtained pups grew up normally without evidence of premature death. This suggests, in a sense, that normal embryos are selected during embryonic development. It is thus essential not only that we refine the culture conditions to increase the success rate of oogenesis, but also that we select in advance competent oocytes/embryos before transferring them to surrogate mothers.

Clear Differences Between In Vivo and In Vitro Oogenesis

Regardless of whether in vitro oogenesis is accomplished in the organ culture system or the reconstituted ovary system, one of the clear differences from in vivo oogenesis will be the formation of primordial follicles, the most immature type of follicles. Histologically, primordial follicles are composed of oocytes surrounded by a monolayer of squamous granulosa cells and located in the cortex of the ovary. They remain strictly dormant (by a mechanism described below) and are sporadically activated in response to environmental cues. The balance between dormancy and activation provides periodical production of oocytes. However, in in vitro oogenesis, almost all oocytes grow up synchronously without resting at the dormant state (Hikabe et al., 2016; Morohaku et al., 2016). Histologically, it is very rare to observe oocytes surrounded by a monolayer of granulosa cells in in vitro oogenesis (Fig. 4). These observations lead to two biologically interesting points. (1) The primordial follicle stage is not essential for functionality of oocytes. (2) In vitro culture is apparently lacking in factors necessary for primordial formation. Since

primordial follicle formation is accomplished by the interaction between oocytes and surrounding somatic cells, not only germ cells but also somatic cells in the culture system must be evaluated more carefully.

Oogenesis In Vitro in Humans

From ethical and clinical points of view, it is less feasible to use human fetal ovaries for developing a culture system that produces oocytes. Rather, it would be more beneficial for patients with infertility to obtain mature oocytes from immature types of oocytes, such as those encapsulated in primordial, secondary and preantral follicles. So far, MII oocytes have not been successfully obtained from primordial follicles. This is partially because the follicles are strictly dormant, since the follicles function as an oocyte storehouse to ensure the longevity of female reproductive life. The stubborn dormancy of the primordial follicles sometimes disturbs in vitro maturation. Therefore, the first step is to trigger follicular activation in the primordial follicles. Based on genetic analysis in mice, several molecules and signaling pathways have been identified. The Foxo3 protein plays a central role in keeping oocytes in the primordial follicles dormant. Disruption of *Foxo3a* causes an acceleration of follicular activation, which results in early exhaustion of the primordial follicles. The activity of the transcription factor is controlled by subcellular localization during follicular activation: Foxo3a is localized in the nuclei of the dormant oocytes, and is exported to the cytoplasm upon follicular activation. The localization is regulated by PI3K-AKT signaling, activation of which eliminates nuclear Foxo3. The signaling is usually antagonized by Pten, a phosphatase for phosphatidylinositol (3,4,5)-trisphosphate (PIP3) in the primordial follicles, but upon activation by an external cue it triggers follicular activation. Based on this background, a research group lead by Hsueh cultured pieces of human ovarian tissues with pharmaceutical reagents, followed by transplantation under the kidney capsule of immunocompromised mice. When a Pten inhibitor (dipotassium bisperoxo(5-hydroxypyridine-2-carboxyl)oxovanadate: bpV) was administered, the number of antral follicles increased up to 27 times compared to that in the controls (Li et al., 2010). In addition, a PI3K-agonistic phospho-peptide (740Y-P) had a synergistic effect on follicular activation. However, the artificially activated follicles often exhibited aberrant growth. Therefore, further refinement will be needed for the initial follicular activation.

Among attempts to mature oocytes in culture, the secondary follicle stage is the most immature stage yet used in the successful production of MII oocytes in primates. The secondary follicles are composed of oocytes surrounded by at least two layers of granulosa cells. In these early structures, the stage is about to switch from a gonadotropin-independent state to a gonadotropin-dependent state. In response to FSH, the follicles vastly increase in size, for example from 150 μ m to 20 mm in diameter, with granulosa cell proliferation and oocyte growth. To reproduce the remarkable morphology, there is a great demand for 3D culture systems that can yield mature oocytes. Among the several methods for reconstituting 3D culture systems, the method using alginate hydrogel currently seems to be the most sophisticated approach for the production of mature oocytes (Xiao et al., 2015). Using this method, MII oocytes were successfully obtained from secondary follicles under a 3D culture system. For the possible ethical implications, it has not yet been evaluated whether the in vitro-matured MII oocytes are capable of fertilization followed by development to term. Instead, culture experiments using nonhuman primates have demonstrated that the in vitro-matured oocytes were fertilized and developed to the morula stage (Xu et al., 2013).

Human Primordial Germ Cells From ES/iPS Cells

One of the ultimate goals in reproductive biology is to reconstitute gametogenesis using pluripotent stem cells in humans. Since a possible strategy has been presented in mice, efforts are underway to adapt the system to humans. Indeed, despite the species difference, it has now become possible to derive human PGCLCs from human ES/iPS cells (Irie et al., 2015; Sasaki et al., 2015). As in the mouse system, BMP and Wnt signaling play key roles in PGC specification in humans. It is interesting that the signaling cascade triggering PGC specification is conserved across the mammalian species. Human PGCLCs largely mimic gene expression and epigenetic modifications in PGCs in vivo. In addition to the ethical implications, however, it is also technically difficult, at the moment, to derive eggs and sperm from human PGCLCs. Since PGCs proceed to gametogenesis in the gonad, signals from gonadal somatic cells, e.g., fetal granulosa cells and fetal Sertoli cells, must be reconstituted in vitro. In the mouse system, the signals are provided by fetal ovarian cells obtained from a number of embryos, which are not available in humans. It is thus necessary to find a way to replace the cells/signals supporting gametogenesis in culture.

SEXUAL DEVELOPMENT

Orgasm

Mihaela Pavličev, Cincinnati Children's Hospital, Cincinnati, OH, United States

Description of the sexual peak, the orgasm, has been dominated by the human experience. Even so, the definitions of what orgasm entails vary broadly, in spite of the general intuitive recognition of the phenomenon. The descriptions range from those focusing on the subjective sensation, the release of neural tension, endocrine effects, or the externally observable changes, such as involuntary muscular contractions (Mah and Binik, 2001). This multitude of descriptions reveals the complexity of the phenomenon, as well as individual variation and highly subjective experience of human orgasm. Orgasm, however, most likely is not a human-specific trait, but much less is known about how common orgasm is across mammalian species. This is at least in part because the current description of orgasm is strongly associated with the characteristics observed and experienced in humans—often too subjective to be expressed without language—thus comparative work on orgasm has been very scarce. For the purposes of this account, we will delineate the orgasm here as a neuro-endocrine event, alluding to the two main physiological signaling systems involved, that is, the nervous and the hormonal systems. We will start by outlining human male and female arousal and orgasm, as the physiology of these is best understood by far. Next, we will summarize what we know about its presence and the possible roles in other mammals, and finally briefly address some of the historical interpretations.

Physiology of Human Orgasm

In males and females the arousal stage precedes the orgasm. Arousal is triggered either by cognitive or tactile stimulation, and begins with the relaxation of smooth muscles lining the blood vessel walls and subsequent rush of blood into genitalia.

In females, the arousal and orgasm have traditionally been described in four stages: excitement, plateau, orgasm and resolution (Masters et al., 1966). Plateau is the stage in which blood flow into the genitalia is increased, leading to vaginal lubrication and vaginal dilation, as well as clitoral swelling. The clitoris is the female anatomical counterpart of the penis and consists of relatively small external visible parts (glans and prepuce or hood) and an appreciable internal portion (paired bulbs and crura with erectile corpora cavernosa; O'Connell et al., 2005; Puppo and Puppo, 2015). The external part of clitoris is located ventro-laterally from vaginal opening, and in particular the glans clitoris—the most sensitive part of clitoris—is positioned at some distance ventral to the vagina. In addition to the involvement of the smooth muscles lining the vessels, the female orgasm manifests itself as involuntary rhythmic muscle contractions of pelvis, uterus and vagina as well as the anus. The majority of women report that stimulation of external clitoral parts, in particular the highly sensitive glans clitoris, is required for the transition from arousal to orgasm (Herbenick et al., 2017; see below for other sensitive regions, such as cervix). The mechanism that underlies the transition from arousal to orgasm is however not understood.

In male arousal the blood rushes into penile *corpus cavernosum*, leading to penile erection. Erection is followed by the ejaculation of sperm from the penis. Physiologically, sperm release consists of two stages; the emission, during which the seminal fluid is collected in the prostatic part of the urethra, and the ejaculation from the penis. We equal here the later stage, the ejaculation, with male orgasm, as the two typically coincide in healthy males. However, the research field is not in complete agreement on this topic (Alexander et al., 1993). Some pathological disorders affect ejaculation and the experience of orgasm independently, which suggests that they are regulated by, to some extent, distinct mechanisms. Arousal, emission and ejaculation are a complex coordinated interplay of several smooth muscles of the ducts epididymis and vas deferens, which connect testes with urethra, further of the seminal vesicle, prostate and several sphincters that likely contribute to accumulating the pressure, with which semen exits penis at ejaculation. As in female orgasm, also male orgasm/ejaculation includes the involuntary action of striated pelvic muscle, the perineal muscles and the anal sphincter. It likely involves more than surpassing a distinct threshold of arousal. Again, the mechanisms that trigger ejaculation/orgasm are currently not understood.

Neurobiology of Human Orgasm

Some of the neurobiological mechanisms involved in mediating arousal and orgasm are known (reviewed in Komisaruk et al., 2006). Genitalia are innervated by the cranial and spinal nerves, integrating the neural connections of autonomous (involuntary) and the somatic nervous systems. Most generally, it is thought that both parts of autonomous neural system are involved in the control of sexual activity: the parasympathetic slow-acting system in arousal, and the sympathetic quick-acting system in actual orgasm. The parasympathetic innervation of genitalia is provided by the cranial *vagus* nerve (Komisaruk et al., 2004) and the sacral pelvic neural fibers, the later associated with pudendal spinal nerve (but see recent suggestion that the pelvic fibers may in fact be

part of the sympathetic system; [Espinosa-Medina et al., 2016](#)). The known sympathetic innervation stems from the hypogastric plexus of the lower abdomen, associated with the lower lumbar spinal nerves. The complex peripheral innervation is also reflected in involvement of multiple brain regions, as shown by the neuroimaging studies of the brain during sexual stimulation. The somatosensory innervation of genitalia in both sexes maps to parts of medial cortex ([Komisaruk et al., 2011](#)), whereas the human orgasm itself has been shown to activate numerous additional brain regions. Mapping female and male orgasm (ejaculation) showed activity in hypothalamic nuclei, cerebellum, preoptic area, bed nucleus of *stria terminalis*, amygdala, hippocampus, lower brainstem, and frontal cortex ([Whipple and Komisaruk, 2006](#); [Georgiadis et al., 2007](#); [Komisaruk and Whipple, 2008](#); [Komisaruk et al., 2011](#); [Huynh et al., 2013](#)). These studies also revealed that to a great extent, male and female orgasm-associated brain circuits overlap. Moreover, many of the same circuits have been also associated with male ejaculation in rodents indicating homologous processes across animal species ([Baum and Everitt, 1992](#)), although differences can be seen when the results are compared to primates ([Michael et al., 1999](#)).

Different neurotransmitter-receptor systems transfer information across synapses in different parts of the vertebrate neural system. Most of the information about the specific neurotransmitters that are active during human sexual arousal and orgasm is derived from the side-effects observed when targeting specific neurotransmitters to treat various conditions, such as for example, depression. The known drug classes that affect arousal and/or orgasm include drugs that act directly on transmitter receptors, such as agonists of serotonin receptors or antagonists of inhibitory noradrenalin receptors. Both these drug types enhance aspects of sexual behavior. Furthermore, the drugs that inhibit degradation of transmitter at the synapse, or inhibit its reuptake (e.g., SSRI drug class), have indicated that serotonin and dopamine modifications significantly modulate sexual reaction and orgasm ([Montejo-Gonzalez et al., 1997](#); [Balon, 2006](#); [Higgins et al., 2010](#)).

Endocrinology of Human Orgasm

Along with the numerous neural circuits of the brain mentioned above, orgasm activates also the hypothalamus. Orgasmic activation of hypothalamus triggers a hormonal response of the pituitary, an endocrine gland functionally connecting the two major signaling systems, the neural and the hormonal system. Pituitary develops partially from neuroectoderm and partially from oral ectoderm. Correspondingly, its function is triggered by the neural signal from the brain, conveyed to pituitary either by the direct neural connections (posterior pituitary), or by the signals secreted from the neurons to the hypothalamic vessel plexus, and transferred into pituitary by the blood (anterior pituitary). Orgasm triggers a surge of pituitary hormone secretion in humans, which is particularly pronounced in females ([Exton et al., 1999, 2001](#)). The strongest hormonal surge is that of prolactin, however also a minor surge of oxytocin has been reported ([Carmichael et al., 1987](#)). The physiological significance of these surges is not clear. As the long-term elevation of prolactin (hyperprolactinemia) is known to inhibit libido, the prolactin surge has been suggested to inhibit promiscuous behavior in females ([Kruger et al., 2002](#)) after coitus. However, the fact that women have more pronounced prolactin surge, and at the same time (in contrast to men) lack refractory period after orgasm, suggests that this effect does not exist and thus such adaptive explanation of the prolactin surge is unlikely ([Bianchi-Demicheli and Ortigue, 2007](#)). An alternative suggestion is that the PRL peak is a remnant of evolutionarily older process that induces ovulation and therefore has had a reproductive function in the evolutionary past (see below). Indeed, prolactin peak occurs at the time of normal ovulation in women ([Vekemans et al., 1977](#); [Braund et al., 1984](#)). Research suggests that PRL may act on ovaries to enhance expression of receptors for luteinizing hormone (LH), the hormone inducing ovulation, and prolong the life span of corpus luteum ([Freeman et al., 2000](#)). Human studies have suggested that women with decreased prolactin levels tend to have shorter luteal phase ([Kauppila et al., 1988](#)). This effect of prolactin is consistent with the role of prolactin in rodent ovarian cycle, which will be discussed further in the section on evolution of orgasm. Mechanistically, the prolactin peak is likely a consequence of brief interruption of dopamine signaling in the hypothalamus, where dopamine constitutively inhibits prolactin secretion, thus dopamine inhibition (for example due to transient increase in serotonin signaling) can account for the prolactin surge ([Bianchi-Demicheli and Ortigue, 2007](#)). The existence of orgasm-associated surge of the second pituitary hormone, oxytocin, has been variably reported ([Kruger et al., 2003](#)) and is possibly a consequence of a different signaling pathway—namely due to projections of the separate neuronal signals from the genitals and breast to the same brain region in the hypothalamus ([Cross and Wakerley, 1977](#)). The reproductive functional significance of oxytocin is likely found in causing the contraction of the myo-epithelial cells in breast milk glands as well as in the reproductive tract, involved in milk ejection in the breast, and propagation of the egg cell in the Fallopian tubes (and fetus during labor) through the reproductive tract. The social function often attributed to oxytocin is that of enhancing partner bonding, in analogy to what is observed in rodents ([Carter, 1992](#); [Witt et al., 1992](#); [Cho et al., 1999](#); [Razzoli et al., 2003](#)). Yet, the orgasm-associated surge reported for humans is not only variably detected, but also small (~1.3-fold change in female orgasm; [Carmichael et al., 1987](#)) relative to the experimental dosages in rodents (up to 10-fold change in experimental settings showing effect on social behavior in rats; [Witt et al., 1992](#)). Given that oxytocin is suggested to reinforce future trust and sexual behavior also in humans, it is not clear whether indeed the weak orgasm-associated increase in oxytocin contributes to these effects, or whether they rather stem from other aspects of intimacy.

Types of Orgasm

Whereas men perceive orgasm relatively uniformly, women report different types of orgasm associated with stimulation of different parts of genitalia ("vaginal", "cervical" vs. "clitoral" orgasm, Grafenberg-spot). The innervation of genitalia described above involves

separate branches supplying different parts of the genitalia, and these all likely respond to stimulation. There is, in addition to spinal nerves, evidence for innervation from cranial *vagus* nerve, which has been suggested to account for cervical orgasm (Sansone et al., 2002; Komisaruk and Sansone, 2003; Komisaruk et al., 2004). Moreover, it is important to realize that the externally visible glans clitoris is only a part of the clitoris, which is much larger and extends internally dorsolateral, parallel to the urethra and also to the ventral vaginal wall (O'Connell et al., 2005; Puppo and Puppo, 2015). It is thus likely that vaginal penetration can achieve indirect stimulation of internal clitoral parts, leading to perception of the ventral vaginal side as a “G-spot”, so called after the German physician Graefenberg (1950), who studied the role of urethra in female orgasm.

Comparative Biology and the Evolutionary Origin of Orgasm

To identify the evolutionary origin of any trait entails recognizing the corresponding (homologous) trait in different species, and subsequently identifying the last common ancestor of those lineages, in which the trait exists. Identifying orgasm in nonprimate species however is difficult. This is because research on orgasm has been primarily conducted in primates, generating a primate-specific definition, which captures lineage-specific characteristics that may be difficult to detect or even be irrelevant in other animals, even though some authors report putative cases of nonprimate orgasm (Pomeroy, 1972; Pfaus et al., 2016). It may be useful to remind the reader that evolution works by a combination of inheritance and modification of traits, and therefore traits that are shared among species, will nevertheless have many species-specific modifications. If these modifications within a certain species (such as human) are considered as a necessary part of the definition of a trait, this precludes the identification of the trait in different species. For this reason, little systematic comparative work has been done to examine the presence, or the role, of orgasm across mammalian species apart from primates. It is very unlikely that the physiological basis of orgasm originated in human, or primate lineage. Rather it is likely that the ancestral trait has acquired modifications in our lineage that make it seem human-specific, and may even have acquired additional roles. It is useful here to consider female and male orgasm separately.

Female Orgasm

The human female orgasm, in contrast to male orgasm, is not necessary to conceive. Indeed, a very high percentage of women do not experience orgasm regularly during reproductive (i.e., penetrative) sex (Hite, 1976; Lloyd, 2005). To explain its existence in humans, various reproductive roles have nevertheless been suggested, by which the presence of female orgasm would positively affect the number of offspring. These roles range from enabling mate choice (Alcock, 1980; Puts et al., 2012), to bonding, or enhancement of sperm transfer (Levin, 2011a, 2011b), to name a few. In spite of efforts, so far no evidence could be found for the current presence of such effects of orgasm on reproductive fitness (Levin, 2011a, 2011b; Zietsch and Santtila, 2013). Here it is important to note that the putative role of female orgasm in humans—whether the female orgasm presently has a (reproductive) role or not—cannot be used as explanation for its origin. What is required is to find and study the trait in other species. This is because the function of a trait often changes during the trait's evolution, and thus evidence is required that the ancestral role was the same as the current role. To answer the question about the origin of female orgasm, it will be necessary to study the presence and evolution of the trait in phylogenetic context.

The most comprehensive discussion of the current hypotheses on evolution of female orgasm has been published by Elizabeth Lloyd. In her 2005 book *The Case of Female Orgasm*, Lloyd (2005) critically reviewed 21 existing theories of origination and maintenance, specifically of female orgasm. Lloyd pointed to the crucial difference between sexes in how closely orgasm is associated with reproductive sex: whereas achieving orgasm in men is effective in reproductive sex, it is highly ineffective in women. Lloyd argued that this makes the explanations based on direct reproductive effects of female orgasm implausible: female orgasm is more efficiently attainable by masturbation or homosexual intercourse, than with reproductive sex. Systematic evaluation of 21 hypotheses based on the evidence that their authors provided, led Lloyd to reject all but the *by-product* hypothesis (Symons, 1979). This hypothesis states that the female orgasm originated and is maintained (in spite of having no function), because the male orgasm is required for reproduction. To understand this hypothesis, it is necessary to know that the male and female genitalia share many of their developmental pathways, that is, the female clitoris is homologous to the male penis. If the underlying genetic program for phallus finds itself in a female individual, the phallus grows into a clitoris, but in a male, it is modified to grow into a penis. As this genetic basis acquires a characteristic that is necessary in one of the sexes, as long as it is not deleterious in another, it is maintained also when it is only required in one sex. Another example for such “vestigial” trait are male nipples. Males do not need them, however the nipples are maintained because males and females have almost identical genomes. Of course some of the adult morphology did become decoupled between males and females: male and female genitalia do look different, penis is larger, and female nipples are as well. But because they are sharing much of the same genetic-developmental program, the hypothesis suggests that the physiology of orgasm simply was not lost in females, because it is crucial when it occurs in males, and does not hurt the female either. The origin and necessity of orgasm in males is thus suggested to drive the origin and maintenance of the orgasm in female. Note that this hypothesis therefore implicitly suggests that female orgasm is as wide spread across species with internal fertilization, as the male orgasm.

Pavlicev and Wagner in 2016 proposed a new hypothesis for the evolutionary origin of female orgasm (Pavlicev and Wagner, 2016; Wagner and Pavlicev, 2017). The authors suggested that human female orgasm is derived from the ancestral neuro-endocrine

signal, which was involved in inducing ovulation during copulation. This mechanism is still maintained in many mammalian species, where ovulation only occurs after an external trigger, often the tactile stimulation during copulation. These so-called induced or reflex ovulators include many carnivores (cats, ferrets, etc.), camels, rabbits and shrews (Bakker and Baum, 2000). In contrast to induced ovulators, humans are spontaneous ovulators, ovulating on an endogenous rhythm, independent of external stimulation. Pavlicev and Wagner noted similarities between the neuroendocrine reflex involved in induced ovulation, and that of the orgasmic neuroendocrine surge and suggested that the signal which triggers pituitary hormones in human female orgasm still carries a signature of the signal that triggers ovulation (via pituitary) in induced ovulators. To support the hypothesis, the authors have shown that induced ovulation is phylogenetically older and thus may have been a predecessor of spontaneous ovulation. As traits lose functions during evolution, their remnants may still remain. Additional evidence is seen in female genital morphology: coincidental with evolution of spontaneous ovulation, also the position of strongly orgasm-triggering glans clitoridis has changed. In species, which require induction by copulation, the glans clitoridis is positioned within copulatory canal where it gets directly stimulated during copulation, whereas in the species that ovulate spontaneously, the clitoris tends to be removed from the copulatory canal. The latter, at the same time, may explain the rarity of female orgasm during reproductive (i.e., penetrative) sex.

An interesting mechanistic insight into the function of copulation-induced reflex may come from laboratory rodents. Mouse is a spontaneous ovulator with very shortened life span of the *corpus luteum* in nonpregnant state. *Corpus luteum* is necessary for implantation, however. The way to prolong the life span of corpus luteum in mice is copulation. If the copulation is sterile, mice still show a long luteal phase in absence of pregnancy (so-called pseudopregnancy). Most interestingly, the mechanism mediating this effect is the induction of high levels of pituitary prolactin. Thus, while mouse ovulation is not copulation induced, the mouse implantation is. This system might be considered as a different derived phenotype from that in primates, based on the same basic mechanisms (copulation-associated prolactin surge acting on ovary).

Male Orgasm

The male orgasm is associated with ejaculation and sperm transfer, and therefore crucial for reproduction. Prompt ejaculation of relatively large amount of sperm thus is generally assumed to be a sufficient explanation for the origin and persistence of orgasm-like impulse in species with internal fertilization. Indeed, erection and ejaculation are widely spread across tetrapods, in particular in amniotes, that is, reptiles and mammals. As mentioned above, some of the neural brain circuits involved in ejaculation are shared at least between rodents and humans, indicating homology of neural regulation.

Historical Cornerstones of Research on Human Orgasm

The irregularity of female orgasm during intercourse has intrigued thinkers since the ancient times. Already Aristotle reflected on the question whether or not female orgasm plays any role in reproduction (reported in Leroi, 2014). Early on, features of female sexuality, including the lack of orgasm during intercourse, has been strongly associated with women's psychological state, and sexual massages were used as treatment for hysteria; *hysteria* standing for a very general description of female mental and behavioral disorders (psychosexual connotation is still reflected in the word *hysterectomy*, meaning uterine removal). This notion was particularly influentially crystalized in the writings of Sigmund Freud, the Viennese founder of psychoanalysis. Freud's work on mental disorders laid great emphasis on the experiences during early development, as well as specifically on sexuality. With respect to female orgasm he proposed a natural developmental succession from infantile clitoral to mature vaginal orgasm (Freud, 1905). The grave consequence of this persuasive concept was the pathologization of the absence of vaginal orgasm during reproductive sex. The lack of vaginal orgasm has become interpreted as a signature of mental immaturity, of women stuck in a childlike sexual state—quite overlooking the fact that the lack of vaginal orgasm is rather the norm than a deviation. One of the early remarkable woman sexologist was Marie Bonaparte (1933). Herself a psychoanalyst, she openly opposed Freud's concept, arguing that glans clitoridis remains the main source of mature female orgasm, and that the lack of orgasm during reproductive sex is due to the lack of clitoral stimulation during penetrative sex, deriving from the placement of the clitoris at distance from the vagina. Remarkably, she collected over 200 individual measurements of the distance between vagina and clitoris in 1930s, and found a correlation between that distance and a decreased rate of copulatory orgasm (a dataset more recently re-evaluated by Wallen and Lloyd, 2011). Best known empirical research on human sexuality and orgasm from the 20th century is undoubtedly that by the zoologist Alfred Kinsey from Indiana University (Kinsey et al., 1948, 1953), followed by the rich work of William Masters and Virginia Johnson, at Washington University in St. Louis (Masters and Johnson, 1960; Masters et al., 1966, 1974, 1993; Kolodny et al., 1979). An important contribution to the body of knowledge on female sexuality, came also from Shere Hite. In a comprehensive review of female sexual experience Hite was the first to document the high percentage of women that rarely or never experience orgasm in penetrative sex—thus considered dysfunctional according to Freud's theory—however are perfectly able to do so in masturbation (Hite, 1976). From the 1970s to 1990s, the evolutionary theories of female orgasm were discussed by a wide range of authors from the ethologist Desmond Morris (1967), the behavioral biologist John Alcock (1980) to the paleontologist Steven J. Gould (1991). With the exception of the work of Symons, Gould and Lloyd, attempts to explain the evolution of orgasm have been predominantly adaptationist, meaning that they aim to explain the origin of female orgasm by its proposed current utility in humans (Wagner

and Pavlicev, 2016, 2017). This debate is synthesized in the influential book by Elisabeth Lloyd (2005). Major contributions to understanding of the physiology of human orgasm were made starting in the 1990s by Barry Komisaruk and collaborators, some of which are documented above.

Glossary

Allele One of two or more alternative forms of a gene, located at the same position on a particular chromosome.

Autosome Any chromosome apart from a sex chromosome, usually occurring in a pair.

Heterochromatin Condensed chromatin from which gene expression is repressed.

Mutation Change in the DNA sequence, including insertion or deletion.

Pseudoautosomal region (PAR) Region of sex chromosomes that pairs and recombines during meiosis.

Pseudogene A copy of a gene that has lost some of its function.

Recombination Exchange of genetic material between paired chromosomes during meiosis.

Recessive mutation Mutation that impacts function only if occurring on both gene alleles, or in males if occurring on an X- or Y-borne gene.

Sex chromosomes Chromosomes that differ between males and females, defined by the presence of a sex-determining gene on one.

Sex-determining gene Gene located on one sex chromosome that triggers development of the embryonic gonad into either a testis or ovary.

Therian mammal Live-bearing mammals, comprising the eutherian (or placental) mammals and marsupials.

Introduction

In most mammals, sex is determined genetically by an XX female: XY male sex chromosome system. The Y chromosome is small and specialized for functions in male sex and reproduction. It bears a dominant sex-determining gene (called *SRY*) which is expressed in early embryogenesis to trigger a complex regulatory cascade that culminates in testis development. In the absence of the Y chromosome, there is no *SRY* gene and ovary development is initiated.

Live-bearing mammals are divided into two main groups: eutherians and marsupials, collectively called therian mammals. The therian X and Y chromosomes evolved from a normal pair of autosomes by a process of Y chromosome degradation after recombination with the X chromosome was suppressed ([Fig. 1](#)). Consequently, the therian X and Y chromosomes differ from each other in size, structure and gene content ([Fig. 2](#)). All that remains of the once extensive homology between the X and Y chromosomes are a few gene pairs and a small pseudoautosomal region (PAR) that is integral to sex chromosome pairing and segregation at male meiosis. The human PAR contains 24 genes.

X Chromosome: Tailored for Sex

In humans, the X chromosome is 156 Mb and bears 841 protein coding genes and 639 noncoding genes ([Ensembl release 89](#)). The gene density (number of genes per megabase) is about half that of the autosomal average due to an increased density of interspersed repeats.

Enriched for “Balls and Brains” Genes

The genes of the X chromosome have a diverse range of conserved functions in therian mammals, but are enriched (relative to autosomes) for genes associated with sex and reproduction. This sex and reproduction bias was not evident in the gene complement of the ancestral autosome from which the eutherian X chromosome evolved, suggesting that specialization for reproductive functions evolved more recently on the X chromosome ([Julien et al., 2012](#)). It appears that this specialization may have continued after the divergence of the rodent and primate lineages, with the independent emergence in human and mouse of X-borne genes with testis-dominant expression ([Mueller et al., 2013](#)).

The X chromosome is also enriched in genes that function in the brain ([Soumillon et al., 2013](#)). In humans, X-borne genes have higher expression in the brain relative to autosomal genes, and a greater proportion of X-borne genes are expressed in the brain than in other somatic tissues. Intellectual disability associated with X-borne genes is 3.5 times more prevalent than that associated with autosomal genes. Males are predominantly affected by X-borne intellectual disability because they have a single X chromosome, so recessive mutation of an X-borne gene is not protected against. In females, the presence of a nonmutated copy on at least one X chromosome is adequate to protect against disease caused by recessive mutations (reviewed in [Deng et al., 2014](#)).

Fig. 1 The generation of evolutionary strata on the human sex chromosomes. Different colors indicate different evolutionary strata, with pale gray representing the PAR. Orange bars represent recombination. Arrows within the chromosomes show inversions on the Y chromosome. (A) The ancestral autosome pair underwent recombination along its length. (B) The sex-determining gene, *SRY* (black), emerged ~180 mya to define the proto-Y chromosome. Spermatogenesis and associated male-benefit genes accumulated near *SRY*, facilitating their transmission only to males. Inversion of the Y chromosome region including *SRY* suppressed recombination, creating evolutionary stratum 1 on the X chromosome (purple). (C) Without recombination with the X chromosome, deleterious mutations accumulated on the Y chromosome leading to loss of gene function, accumulation of heterochromatin and reduction in physical size. (D) A second inversion on the Y chromosome ~117 mya extended the section in which recombination was suppressed between the X and Y chromosomes, creating evolutionary stratum 2 (green). Together, strata 1 and 2 on the X chromosome form the X-conserved region that is common to eutherians and marsupials (Fig. 2). The Y chromosome degenerated further. (E) An autosomal block was fused to the X and Y chromosomes, extending the PAR. This represents the added region of the eutherian sex chromosomes (Fig. 2). (F) A further inversion on the Y chromosome created stratum 3 (pink). (G) The degeneration of the Y chromosome continued. (H) A final inversion on the Y chromosome occurred in the primate lineage ~25–40 mya, leading to the emergence of stratum 4 (yellow) and further reduced the PAR. (I) The contemporary human sex chromosomes. There is possibly a fifth stratum (not shown) (Lahn and Page, 1999; Cortez et al., 2014). Chromosomes not drawn to scale.

Fig. 2 Sex chromosomes in representative mammals. (A) The mammalian XY chromosomes evolved from a pair of autosomes in a common ancestor of the eutherians and the marsupials when the *SRY* testis-determining gene (black band) evolved from the *SOX3* gene (purple band) to define a new proto-X and -Y chromosome system. The *SOX3* gene is conserved on the eutherian X chromosome. The ancestral section of the XY pair, common to eutherians and marsupials, is called the X- and Y-conserved region (X/YCR) (light blue). After *SRY* emerged, recombination (represented by orange bars) was repressed by a series of inversions on the Y chromosome (Fig. 1). (B) A section of an autosome was fused to the PAR of the sex chromosomes after divergence of the marsupials, forming the X- and Y-added region (X/YAR) (orange). Recombination was also repressed between the XAR and YAR. (C) The contemporary sex chromosomes in opossum, mouse, macaque, and human. The mouse Y chromosome accumulated extensive regions of repeat sequence (yellow) (Soh et al., 2014). The human Y chromosome accumulated repeats (yellow), but also heterochromatin (gray) (Skaletsky et al., 2003). The X chromosome is conserved within primates. The mouse X chromosome has conserved gene content, although the order has been rearranged. Ampliconic repeats have emerged independently on the mouse and human X chromosomes (green) (Mueller et al., 2013). Recombination continues between the X and Y chromosomes within small PARs in eutherian mammals (pink). The marsupial XY pair no longer recombines. Centromeres are dark gray. Divergence dates shown at nodes. Lineage specific chromosome sizes are drawn to scale. Chromosome sections are not drawn to scale.

Many X-borne genes are expressed in both brain and testis, but not in other tissues. This bias may have arisen when X-borne genes with broadly expressed regulatory roles acquired new expression profiles, allowing them to be expressed more specifically in the brain and in association with male sex development. Because males have only one X chromosome, any change in an X-borne gene that is favorable to males is exposed to positive selection, and so more likely to become fixed in the population. It is suggested that the accumulation of “balls and brains” genes on the X chromosome may have been accelerated by sexual selection, where enhanced reproductive success of males results from their attractiveness to females rather than from any intrinsic adaptive fitness (reviewed in [Graves et al., 2002](#)).

X Chromosome Inactivation: Silencing One X in Females

X chromosome inactivation occurs in female therian mammals, where gene expression from one X chromosome is silenced in the somatic cells of females. The silent X chromosome condenses to form a distinct compact body (Barr body) within the nucleus. X chromosome inactivation is controlled by an elaborate molecular mechanism that is not fully understood, although seems to involve both structural and sequence elements of the X chromosome. In eutherians, a noncoding gene (called *XIST*) is expressed from the X chromosome chosen for silencing. The *XIST* RNA then coats the chromosome and recruits an array of protein complexes that mediate silencing. The mechanism underlying the accumulation and spreading of *XIST* RNA along the X chromosome is yet to be resolved, although long interspersed nuclear elements (LINE1s) on the X chromosome may be implicated. LINE1 element density on the human X chromosome is almost twofold that of the autosomes. LINE1 elements are particularly enriched around the *XIST* gene and in regions where silencing is most effective in human and several other eutherian species (excluding mouse). This is consistent with a role for LINE1 elements in localization of *XIST* RNA on the X chromosome in these species, although direct binding appears unlikely (reviewed in [Gendrel and Heard, 2014](#)).

Y Chromosome: Male-Specific Gene Acquisition and Divergence

In contrast to the X chromosome, the Y chromosome is small. In humans, it is the smallest chromosome (57 Mb) and bears 63 protein-coding genes and 109 noncoding genes ([Ensembl release 89](#)). It encodes 27 unique proteins, several of them in multicopy.

Specialized for Males

The Y chromosome is specialized for male reproduction (spermatogenesis). As the chromosome bearing the testis-determining gene (*SRY*), the Y chromosome is transmitted only through males, making it the optimal location for the accumulation of genes that are beneficial to males. Reflecting this particular selective pressure, 11 of the 27 unique proteins encoded on the human Y chromosome are expressed exclusively or predominantly in the testis ([Skaletsky et al., 2003](#)). Given this bias toward testis-specific expression, it is not surprising that the main disorder associated with Y chromosome mutations is impaired spermatogenesis (reviewed in [Hughes and Page, 2015](#)).

The genes on the human Y chromosome that do not have testis-specific expression are broadly expressed in a variety of tissues and are involved in a range of regulatory functions, including nucleic acid binding, transcription, and translation. Most of these broadly expressed Y-borne genes have a functional copy on the X chromosome, consistent with a role that requires two copies of these genes to maintain normal function ([Cortez et al., 2014](#)). It was suggested that subtle differences between the X- and Y-borne versions of regulatory gene pairs could potentially contribute to the differential susceptibility of male and females to a range of complex diseases, including cancer, heart disease and autism. This is a largely unexplored area of enquiry, and one that poses significant experimental challenges, not least of which is disentangling genetic from hormonal effects (reviewed in [Hughes and Page, 2015](#)).

Lineage-Specific Structural Divergence

Unlike the X chromosome, the Y displays considerable difference between species in size, proportion of condensed chromatin (heterochromatin) and proportion of ampliconic (inverted or palindromic) repeats ([Fig. 2](#)). This difference is even evident between closely related groups, such as within the primates ([Li et al., 2013](#)).

Over 50% of the human Y chromosome is heterochromatin. The remainder is comprised of ~45% ampliconic repeats. These ampliconic repeats contain nine protein-coding gene families with copy numbers ranging from 2 to 35 ([Skaletsky et al., 2003](#)). The mouse Y chromosome (92 Mb) is nearly twice the size of the human Y chromosome, and is surprisingly different. It has 183 protein-coding genes, almost no heterochromatin (~3%), and is predominantly (~95%) ampliconic repeats. It contains hundreds of copies of testis-specific genes from three gene families. At least a third of these gene copies are actively transcribed and none have homologs in primates, indicating that they emerged after divergence of the primates and rodents ([Soh et al., 2014](#)).

The extent to which structural features of the human or mouse Y chromosome are characteristic of other therian lineages is largely unknown. Sequencing of Y chromosomes is notoriously difficult, due to a combination of low gene content and highly repetitive sequence. Based on Y sequences that are available, there is evidence of abundant (<30 Mb) ampliconic repeats in Y chromosomes of cat and chimpanzee, but not in rhesus macaque. Similarly, the proportion of heterochromatin in the human Y

chromosome far exceeds that of any other sequenced Y chromosome, most of which (mouse, rhesus, chimpanzee, cat, and marsupials) have virtually none (reviewed in [Li et al., 2013](#)).

Conservation of X Chromosome, Degeneration of Y Chromosome

Gene content and order on the eutherian X chromosome is remarkably conserved, as demonstrated by global conservation of the human, horse, pig, cat, cattle, and elephant chromosomes (reviewed in [Livernois et al., 2012](#)). Even on the rodent X chromosome, where rearrangements have altered gene order, the gene content remains similar to that of other eutherians ([Fig. 2](#)). Compared with the eutherians, marsupials have a somewhat smaller X chromosome: 490 protein coding genes and 213 noncoding genes in the opossum, *Monodelphis domestica* ([Ensembl release 89](#)). The marsupial X chromosome shares homology with the entire long arm and part (the pericentric region) of the short arm of the human X chromosome. The remainder of the eutherian X chromosome is an autosome in marsupials. This autosome was fused to the sex chromosomes in the eutherian ancestor and on the X chromosome is called the X-added region ([Fig. 2](#)).

In contrast to the significant conservation of the X chromosome, on the Y chromosome only 18 genes from the ancestral Y gene complement have been retained in at least one therian representative. On the modern human Y chromosome, only five genes are retained from the ancestral Y chromosome. A further 13 genes (2 of which have degraded to pseudogenes) are retained from the autosome added to the sex chromosomes in the eutherian ancestor ([Cortez et al., 2014](#)).

Evolution of Sex Chromosomes

Recombination Repression Leads to Loss of Genes From the Y

The emergence of the testis-determining gene (*SRY*) on the ancestral Y chromosome provided a region of the genome that was only ever inherited in males. This allowed genes beneficial to spermatogenesis and male development to accumulate in this male-specific region, even if detrimental to females. Repression of recombination between the X and Y chromosomes across this region ensured that the cassette of male-specialized genes remained together. Recombination is critical for the purging of deleterious mutations which, arising on a chromosome, can be replaced by recombination with the paired region of the other chromosome. In the absence of recombination, selection can act only on the entire chromosome rather than individual genes ([Charlesworth, 1991](#)). Consequently, mutations accumulate because they cannot be removed. This is what happens to the Y chromosome: it accumulates deleterious mutations that cannot be removed by recombination, ultimately leading to loss of gene function.

The loss of Y-borne genes is accelerated by the elevated mutation rate of those genes, which results from a higher number of germline cell divisions in male spermatogenesis compared with female oogenesis. Loss of nonfunctional DNA from the Y chromosome has no effect on fitness, and so may result in a reduction in physical size. This is evident in the diminished size of the therian Y chromosome. The therian X chromosome is spared from the fate of the Y chromosome because it undergoes recombination in females.

The process of Y chromosome degeneration slows over time. Y chromosomes at more advanced stages of evolution have very few functional genes and so fewer mutations that are exposed to purifying selection. Accordingly, gene loss from the oldest parts of the human Y chromosome proceeded rapidly at first, and then slowed significantly as only a small number of essential genes were retained ([Cortez et al., 2014](#)).

Loss of Y chromosome genes has not proceeded randomly. Analysis of the rates of nucleotide substitution at nonsynonymous sites (where mutation to the DNA changes the protein) compared with synonymous sites (where mutation to the DNA does not change the protein) indicates that some Y-borne genes were subject to positive selection ([Li et al., 2013](#)). Many of these genes have a partner on the X chromosome that is broadly expressed and has regulatory functions, where transcription from a single gene copy may be insufficient for a normal phenotype. In these cases, conservation of the Y-borne gene partner may have resulted from selection to maintain two gene copies.

Evolutionary Strata

Recombination between the X and Y chromosomes was suppressed by inversion events on the Y chromosome, leaving successive regions of the X chromosome recombinationally isolated from the Y chromosome ([Lahn and Page, 1999](#)) ([Fig. 1](#)). These regions are called evolutionary strata and are defined by the extent of divergence between X and Y gene pairs. Divergence is measured by the rate of accumulation of nucleotide changes that do not affect the protein that is coded for (synonymous substitutions). At least four evolutionary strata are readily identifiable on the human X chromosome. On the Y chromosome, it is more difficult to distinguish evolutionary strata due to extensive rearrangements.

The sex-determining *SRY* gene provided the initial focal point for suppression of recombination between the X and Y chromosomes, and so is part of the first evolutionary stratum. Stratum one arose ~180 mya, before split of the eutherian and marsupial mammals. Stratum two arose in early eutherians, after divergence of the marsupials. At about the same time as the emergence of stratum two, an autosomal block was added to the sex chromosomes, extending the PAR. Suppression of recombination between the X and Y chromosomes within the extended PAR formed stratum three, also in early eutherians. Stratum four emerged only in the primate lineage ([Cortez et al., 2014](#)).

X Chromosome Shaped in Testis

In the testis, expression of protein-coding and noncoding genes is more prolific and complex than in other tissues, particularly during spermatogenesis. This is consistent with a hypothesis that the testis provides an environment that is more conducive than other tissues to gene expression, and to the emergence of new genes over time (Soumillon et al., 2013). Evolution of the X chromosome is particularly impacted by the emergence of new genes because of the evolutionary pressures arising from the presence of only a single X chromosome in males.

The X chromosome is enriched for recessive mutations that confer a male benefit. These recessive mutations are immediately open to positive selection on the single X in males, even if detrimental to females (i.e., sexual antagonism). Any detrimental effects of the new alternative gene form (allele) in females will initially be shielded by normal function of the dominant allele. However, as the new recessive allele occurs more frequently in the population, homozygous females (with two copies of the mutant allele) will emerge and female fitness will be affected. From this point, selection favors restricting expression of the allele to males only. The influence of sexual antagonism is highlighted by the prevalence of genes with testis-biased expression on the X chromosome (Soumillon et al., 2013). This applies particularly to genes that have evolved more recently on the X chromosome in repeat regions, where duplicated genes have redundant functions and so are free to evolve new functions (Zhang et al., 2010).

It was proposed that amplification of some male-specific genes on the X chromosome has been driven by the silencing of X- and Y-borne genes early in male meiosis. This silencing, called meiotic sex chromosome inactivation (MSCI), can silence genes on the X chromosome that have critical function both during and after meiosis. Increased copy number of these genes on the X chromosome can accommodate the silencing effects of MSCI by permitting sufficient gene expression. Consistent with this hypothesis, male-specific genes are enriched in the multicopy gene regions of the human and mouse X chromosomes (reviewed in Deng et al., 2014).

MSCI was also hypothesized to be a driving force that relocates genes required for specific stages of spermatogenesis from the X chromosome to autosomes. These genes can then be expressed unaffected by MSCI. This is supported by the observation that in mouse evolutionarily older spermatogenesis genes tend to be located on autosomes if they are expressed after MSCI initiates silencing, but are enriched on the X chromosome if expressed before MSCI (Soumillon et al., 2013; Zhang et al., 2010).

Sex Chromosome Evolution in Real-Time: Rodents Without a Y

Different sex chromosome systems have arisen many times in diverse vertebrate lineages, and are defined by different sex-determining genes. The genes involved in core testis and ovary developmental pathways are largely conserved across vertebrates, and many sex-determining switches have evolved from a mutation affecting function of one of these genes. For example, *SOX3* is a transcription factor with roles in development of the central nervous system and male gonadogenesis. It has evolved into the sex-determination gene (*SRY*) in therian mammals and independently into a different sex-determining gene in a fish (*Oryzias latipes*). Similarly, the transcription factor *DMRT1* has a conserved role in vertebrate male development, and has evolved into a sex-determining gene independently in chicken (*Gallus gallus*), a fish (*Oryzias latipes*), and a frog (*Xenopus laevis*). This suggests that the conserved gonad development pathway has an inherent plasticity that can accommodate a multitude of different sex-determining triggers (reviewed in Graves, 2013).

The plasticity of sex-determining switches is highlighted in some rodent species where the Y chromosome and *Sry* gene have been lost. Two species of spiny rats lost their Y chromosome and *Sry* gene in a common ancestor. It appears that a mutation in the *Sry* gene weakened its function, likely reducing selection to retain *Sry* and, ultimately, the Y chromosome. A conserved ovary suppressing gene (*Cbx2*) has been identified as the novel candidate sex-determining gene. The presence of additional copies of *Cbx2* in male spiny rats suggests ovarian repression as the new (or emergent) sex determination mechanism (Murata et al., 2012), which will define a new sex chromosome system. Similarly, two species of mole vole have lost their Y chromosomes in independent events. It appears that the role of *Sry* may have been destabilized by mutations in another gene integral to the testis-determination pathway, rendering *Sry* (and consequently the Y chromosome) redundant. An alternative sex-determining gene has not yet been identified in mole voles (Mulugeta et al., 2016), but evolution of a new sex chromosome system must have commenced.

The evolutionary trajectory of sex chromosomes is unique in the genome, and begins with the emergence of a sex-determining gene. The disparities between the human X and Y chromosomes reflect a later stage of the evolutionary process. The end of this process has occurred in some rodents with the loss of their Y chromosome. This heralds the emergence of new mammalian sex chromosome systems, demonstrating the robustness of sex determination in vertebrates despite the array of novel sex determining switches.

Genetic Mechanisms of Sex Determination

Dagmar Wilhelm and Andrew J Pask, The University of Melbourne, Parkville, VIC, Australia

© 2018 Elsevier Inc. All rights reserved.

Environmental sex determination (ESD) is believed to be the ancestral state, with genetic sex determination systems evolving later and independently in many lineages. ESD permits skewing of the sex ratio, which can maximize fitness in certain species or under a given set of environmental conditions (Adkins-Regan and Reeve, 2014). Conversely, genetic sex determination is controlled by one or more loci that are located on sex chromosomes and these mechanisms usually result in a stable 1:1 ratio of males-to-females in a population. Species with GSD are not affected by the external environment, which is important for thermo-regulated, viviparous species such as placental mammals, where sex determination and early sexual differentiation occurs in a controlled environment, in utero.

Sex Chromosome Systems

Sex chromosomes have evolved many times independently, but their evolutionary journey is surprisingly similar. Sex chromosomes develop from a pair of autosomes when one of the chromosomes gains a sex-determining locus. To keep the genes with the sex-specific function together, recombination becomes suppressed around this locus. The lack of recombination results in an accumulation of mutations and accelerated degradation of the sex-specific chromosome (for review: Ellegren, 2011; Graves, 2016). Therefore, the size difference between the sex-specific chromosome and its counterpart is an indication of the age of the sex chromosomes.

There are two main sex chromosome systems: XX/XY, in which the male is heterogametic, that is, carries two different sex chromosomes; and ZZ/ZW, where the female is heterogametic. Typical examples are humans with a XX females and XY males, and birds with ZW females and ZZ males (Fig. 1). However, there are variations to this basic model. For example, some sex chromosomes have evolved by translocations and/or fusions, such as the $Z_1Z_1Z_2Z_2$ -male and Z_1Z_2W -female system in the Adélie penguin (Gunski et al., 2017), and the XY_1Y_2 -male and XX-female system in the catfish *Harttia carvalhoi* (Centofante et al., 2006). One of the most complex sex chromosome systems exists in monotremes, such as the Echidna, with a $X_1X_2X_3X_4X_5/Y_1Y_2Y_3Y_4Y_5$ -male and $X_1X_1X_2X_2X_3X_3X_4X_4X_5X_5$ -female system where the sex chromosomes form translocation chains or rings during meiosis (Grutzner et al., 2004; Rens et al., 2004). In addition, some groups have appeared to have lost a sex chromosome. For example, in the vole *Microtus oregoni* females are XO, whereas males are XY (Ohno et al., 1966; Fredga, 1983). In contrast, in two *Ellobius* species, *Ellobius tancrei* and *Ellobius talpinus*, the Y chromosome is lost and both males and females are XX (Just et al., 1995, 2007). In the Japanese spiny rats *Tokudaia osimensis* and *Tokudaia tokunoshimensis*, as well as the mole vole *Ellobius lutescens*, both the Y and the second X chromosome are absent and all animals are XO (Arakawa et al., 2002; Just et al., 1995).

In addition to their differentiation, the gene content of the sex chromosomes also becomes unique over time. The eutherian Y chromosome harbors the sex-determining locus and contains only a handful of other genes, all of which function in either testis development, spermatogenesis or as basal transcriptional regulators (Bellott et al., 2014). The eutherian X chromosome shows an enrichment of genes involved in testis and brain function (Graves et al., 2002). This is due to altered selective pressures placed on sex chromosomes, stemming from their hemizyosity in males. Thus, in males, mutations on the X chromosome that confer a male selective advantage can be rapidly selected for even if they would be recessive in the heterozygous state. The Y chromosome

Fig. 1 Sex determination mechanisms in vertebrates. Vertebrate phylogeny showing the various methods of sex determination in each major lineage. Mammals have an exclusively GSD sex determination mechanism involving X and Y chromosome. Birds and reptiles show a broad range of mechanisms including GSD with exclusively ZW sex determination seen in birds but both XY and ZW systems and ESD seen in the reptiles. Amphibians appear to have largely GSD mechanisms with most species having cryptic sex chromosomes. Examples of amphibians with both XY and ZW systems have been described. Finally, fish have a broad array of mechanisms ranging from ESD to GSD including XY, ZW, and polygenic systems. Pictures obtained from <https://pixabay.com/>.

cannot contain any factors required for female function, so the only genes that remain are those that confer a male advantage or that are required to exist in two copies in both males and females (Whitworth and Pask, 2016). Similarly, the W chromosome in birds is enriched for female specific factors, owing to its hemizygoty in females (Moghadam et al., 2012).

Polygenic Systems of Sex Determination

In contrast to the XX/XY and ZZ/ZW system, in a polygenic sex determination system, multiple, independently segregating sex determining loci are present due to additional loci in the genome that can influence gonad development. This can arise through alterations of the sex chromosomes or of one of the autosomes, this can include, for example, the translocation of parts of the Y chromosome to an autosome, creating a so-called “neoY chromosome,” resulting in a multiple sex chromosome system.

Polygenic sex determination mechanisms have been described in a various species of fish, insects, frogs, and even mammals. One of the first species for which a polygenic sex determining system has been identified is platyfish (*Xiphophorus maculatus*), which has a male-determining Y system as well as a female-determining W system. In this system males either are XY or YY, and females either XX, XW, or YW (Vollf and Scharl, 2001). This means the hierarchy of these multiple sex chromosomes can be described as $W > Y$. However, this hierarchy is context dependent. For example, in the Western clawed frog *Xenopus tropicalis*, which also possesses three different sex chromosomes, W, Z, and Y, the hierarchy is $Y > W$. Therefore, males are either YZ, YW, or ZZ, and females are ZW or WW (Roco et al., 2015).

Examples of species in which a modification of a sex chromosome resulted in a polygenic sex determination mechanisms are the wood lemming, *Myopus schisticolor*, several species of the South African field mice (genus *Akodon*), and the African pygmy mouse, *Mus minutoides*. All three have an XY sex determination mechanism, but display both XX and XY females. However, the underlying modifications are different between the different species. In the wood lemming a mutation on the X chromosome, designated X*, most likely a structural rearrangement in the short arm of the X chromosome (Xp), results in the inactivation of the testis-determining factor on the Y chromosome. Therefore, three genotypically different females exist, XX, XX*, and X*Y. X*Y females only produce X*-containing oocytes, hence they give birth to daughters only (XX* and X*Y), resulting in approximately three to four-times more females than males in the population (Winking et al., 1981). Similarly, a chromosomal rearrangement of the X chromosome, however most likely a different one to that in the wood lemming, leading to an X* chromosome has been proposed in the African pygmy mouse. In contrast, in at least six species of *Akodon* the Y chromosome independently acquired a mutation resulting in a Y* and the complete failure to activate the male pathway (Bianchi and Contreras, 1967; Hoekstra and Edwards, 2000). Interestingly, sex reversed XY females in most mammalian species display greatly decreased fertility and fecundity (Marin and Baker, 1998). In contrast, in the species mentioned above, XY females are viable and fully fertile.

An example in which an autosome has undergone modifications is the house fly *Musca domestica*. The genome of the house fly consists of five autosomes and X and Y sex chromosomes. The Y chromosome harbors a male-determining factor M (Y^M). However, this factor can also be encoded on an autosome, A^M , or the X chromosome, X^M (Schmidt et al., 1997). In natural populations, male can carry one to several M factors (Hamm et al., 2014). In populations in which M is only on an autosome or the X chromosome, both males and females are XX (Franco et al., 1982; Hiroyoshi, 1964). The immediate downstream target of M is *Md-tra*, which is located on an autosome and exists in two variants, the wild-type allele *Md-tra* and a dominant allele, *Mda-tra^D*. While *Md-tra* is inhibited by M, *Mda-tra^D* is not and hence functions as a female-determining factor even in the presence of up to 3 M factors (Hediger et al., 1998, 2010).

Sex Determining Genes

While downstream genes in the sex differentiation regulatory cascade are conserved, the master sex determining gene that triggers sexual development shows, similar to the sex determination mechanisms, broad variations. The mode of action of this master sex determining gene can be either dosage sensitive, male- or female-dominant.

In mammals, the gene that initiates sexual development was discovered in 1990. The Y linked sex determining region on Y, or SRY gene was identified from analyses of human XY female and XX male patients (Sinclair et al., 1990). Experiments in mice revealed that it was both necessary and sufficient to drive testis development (Sinclair et al., 1990; Koopman et al., 1991). SRY encodes a transcription factor containing a high mobility group (HMG) DNA-binding domain, that gave the name to a whole family of transcription factor genes, the *Sox* (SRY-related HMG-box) family (Bowles et al., 2000). In contrast to *Sry*, which is only present in mammals, other *Sox* genes are conserved throughout the animal kingdom, including unicellular choanoflagellates (King et al., 2008). However, *Sry* is believed to have evolved from *Sox3* (Fig. 2), which is located on the X chromosome (Foster and Graves, 1994). SRY directly upregulates another HMG box gene, *Sox9* (Sekido and Lovell-Badge, 2008). SOX9 is, like SRY, necessary and sufficient to drive testis development in human and mice (Barrionuevo et al., 2006; Bishop et al., 2000; Chaboissier et al., 2004; Foster et al., 1994). As the only conserved domain between the two factors is the HMG domain, it has been suggested that other SOX proteins could function as male-determining factors. Indeed, ectopic expression of either SOX3 or SOX10 in human and mice result in testis development in XX individuals (Polanco et al., 2010; Sutton et al., 2011).

When *Sry* is not present or not functional, an ovary will form and therefore female development will occur. Hence, the female pathway has been seen as the default pathway. Nevertheless, there also is an active process driving ovarian differentiation, and while in mouse no ovarian counterpart for *Sry* has been identified, an ovarian-determining gene exists, for example in goat. Deletion of the

Fig. 2 Mammalian sex chromosome evolution. The sex chromosomes in all species originate from a homomorphic autosomal pair. One gene acquires the ability to determine sex. In mammals, this was the evolution of the *SRY* gene from its X-linked orthologue *SOX3*. Once the sex determination gene has been specified, recombination become restricted around this gene to prevent its cross over onto its chromosome pair. This restricted recombination leads to the accumulation of mutations, deletions and duplications causing the eventual evolution of heteromorphic sex chromosomes. The sex chromosomes also accrue a unique gene content owing to their sex specific distributions. A, Autosome, X, X-chromosome, Y, Y-chromosome. Numbers indicate the time of divergence in millions of years.

gene encoding the forkhead transcription factor *FOXL2* results in testes development instead of ovaries, and therefore female-to-male sex reversal (Boulanger et al., 2014). Similarly, mutation of R-spondin 1 (*RSPO1*) in human can lead to complete female-to-male sex reversal in the absence of *SRY* (Parma et al., 2006). Mice with a null mutation in either *Foxl2* or *Rspo1* “only” display premature ovarian failure and partial sex reversal respectively (Uda et al., 2004; Chassot et al., 2008; Tomizuka et al., 2008), demonstrating clear differences between different mammalian species.

The identification of *SRY* as the male-determining gene in mammals triggered intensive research into the evolution of sex determining genes. It came to a surprise that no other vertebrate has the *SRY* gene. Instead, the first non-mammalian master sex determining gene that was identified in the Japanese rice fish medaka (*Oryzias latipes*) was *Dmy/Dmrt1bY* (DM domain gene on the Y chromosome/doublesex and mab-3 related transcription factor 1b on the Y chromosome) (Matsuda et al., 2002; Nanda et al., 2002). Interestingly, other members of the *Dmrt* gene family were independently recruited as master sex determining genes in other species. These include *Dmrt1* on the Z chromosome in birds, which confers male development using dosage sensitive mechanism (Smith et al., 2009), and *DM-W*, a truncated copy of *Dmrt1* on the W chromosome in the African clawed frog *Xenopus laevis*, which is a female-dominant gene driving ovarian development (Yoshimoto et al., 2008). This relatively widespread distribution of DM genes as master sex determining genes resulted in the suggestions that these could be the equivalent to the mammalian *Sry*. However, further analysis of the *Dmy/Dmrt1bY* in fish uncovered that it is absent in all other fish species studied (Kondo et al., 2003). It became clear that teleost fish not only represent nearly half of all extant vertebrates, but also display one of the widest variety of sex determination mechanisms, including a broad diversity of master sex determining genes. In addition to *Dmy/Dmrt1bY* in medaka, four other promising candidates have been identified to function as the trigger for sex differentiation. These include *amhy* (antiMüllerian hormone on the Y chromosome) in the Patagonian pejerrey *Odontesthes hatcheri*, *amhr2* (antiMüllerian hormone receptor 2) in the pufferfish *Takifugu rubripes*, *gsdf* (gonadal soma-derived growth factor) in *Oryzias latipes*, a species related to medaka, and *sdY* (sexually dimorphic on the Y chromosome) in the rainbow trout *Oncorhynchus mykiss* and most other salmonids (Hattori et al., 2012; Kamiya et al., 2012; Myosho et al., 2012; Yano et al., 2012). Interestingly, none of these four genes encode transcription factors. Instead, two of these genes, *amhy* and *gsdf*, encode for growth factors, one, *Amhr2*, for a receptor, and the last one, *sdY*, for a protein that has homology to interferon regulatory factor 9 (IRF9), involved in SMAD signaling triggered by interferons. This demonstrated that a master sex determining gene does not have to encode a transcription factor to trigger sex differentiation.

Genetic Systems That Can Be Overruled by the Environment

Several groups of reptiles and fish show rapid evolutionary transitions between GSD and ESD mechanisms (Fig. 1; Quinn et al., 2011). Such plasticity in sex determination mechanisms can only occur in species with poorly differentiated sex chromosomes where essential genetic elements have not been lost to one of the sexes. Adding another layer of complexity, some species appear to have both GSD and ESD mechanisms operating concurrently, perhaps representing species at the transition from one mechanism to the other. One such species with both ESD and GSD is the European sea bass (*Dicentrarchus labrax* L.). While genetic mechanisms play a major role in sex determination in this species, elevated temperatures during early development result in masculinization of

fish that would develop into females at standard temperatures (Diaz and Piferrer, 2015). Similarly, in the Australian central bearded dragon lizard (*Pogona vitticeps*), which has a ZZ/ZW GSD system, elevated temperatures during development results in sex reversed genotypic males (ZZ) to phenotypic females (Quinn et al., 2007). Thus, in both cases, temperature can override the gene(s) involved in primary sex determination enabling skewed sex ratios under certain conditions.

Conclusions

From the studies mentioned above, it is clear that the sex determination switch is highly variable across the vertebrates and even between closely related species. In contrast, the underlying mechanisms which then direct the gonadal somatic cells towards either a male or female fate remain highly conserved. This begs the question of *why sex determination mechanisms are so variable*? It is clear that ESD mechanisms can increase fitness for some species where a certain temperature or skewing of the sex ratio leads to increased survivability. But it remains unclear why species with GSD would evolve such a variety of mechanisms and so rapidly transition from one gene driven system to another. This is especially puzzling given that determining sex correctly is arguably the single most important developmental trait in conferring fitness. Thus, we would predict that sex determination genes should be one of the most highly conserved aspects in our genomes.

Defining the mechanisms of sex determination, especially in species where it is rapidly evolving, is going to be critical for our understanding of why sex is so variable. The tractability of next-generation sequencing is likely to have a large impact on our understanding of vertebrate GSD mechanisms over the coming decade. It is now possible to sequence entire genomes from males and females in a population with no discernible sex chromosomes and simply compare the sexes to identify the genes which might be triggering the sex determination cascade. Such approaches can also be coupled with transcriptome sequencing of the developing gonad to identify not only the sex determination switch genes, but also the downstream genes and pathways activated in early sex fate choices across disparate species.

Psychological Effects of Sex Differentiation

Matthew S Bramble, Neerja Vashist, and Eric Vilain, Children's National Medical Center, Washington, DC, United States

Introduction

Sexual differentiation by definition is the process by which gonadal hormones such as estrogens and androgens influence the development of sex typed characteristics downstream of sexual determination, that is, the development of one's testis or ovaries. During in utero mammalian development, the testes begin secreting testosterone during mid-late gestational weeks. During this active androgen exposure, tissues such as the external genitalia, which are androgen sensitive, become masculinized (Hines, 2003). Both XX and XY genital tissues are typically responsive to androgen, and if stimulated this results in penis formation in male fetuses and clitoral enlargement in female fetuses, a condition discussed in greater detail throughout the review. Gonadal hormones have been shown to act in two distinct ways, either through organizational or activational effects. The organizational effects are permanent nonreversible effects, while the activational effects are shorter-lived nonpermanent effects (Arnold, 2009). This organizational/activational hypothesis was largely developed in the 1950s with the publication by Phoenix et al. (1959), where it was demonstrated that in utero testosterone exposure on genetically female Guinea pigs caused permanent changes to their adult sexual behavior. These changes resulted in the female Guinea pigs taking on more male-typical sexual roles, a behavioral modification that was irreversible. Organizational effects of hormones occur during a distinct window in development called the critical period where the presence of specific hormones can result in long lasting effects. In rodents this critical period is during late gestation or shortly after birth (Arnold, 2009). The exact critical period in human development is less exact, but is believed to be during high levels of early testosterone secretions, between gestational weeks 8–24 and up to 6 months after birth (Hines, 2003). During in utero development some of the organizational effects caused by testosterone on the body include but are not limited to, phallus growth, internal reproductive organ development and the overall proper formation of the external genitalia (Hines, 2003). In addition to the physical effects of hormonal organization, there are also numerous effects on the central nervous system that are thought to be organized by the exposure to gonadal hormones, namely testosterone, during the critical period of human development. Testosterone exposure on the mammalian brain generates sex differences in anatomic structure of various regions such as the bed nucleus of the striatum terminalis (BNST) along with altering neural cell densities in additional brain regions by affecting the rate of cell death. In addition to anatomic changes in the brain as a result of testosterone exposure, it has also been shown that androgens can alter gene expression, DNA methylation and other epigenetic signatures in various regions of the central nervous system (CNS) (McCarthy, 2010; Ngun et al., 2011). Some of these anatomical, genetic and epigenetic sex differences between the male and female brain, which are triggered by androgen stimulation likely affect downstream behaviors and other cognitive measures. Here we will review some of the more heavily studied aspects of the psychological effects of sexual differentiation such as sexual orientation, toy play preferences and other cognitive abilities that seem to be heavily influenced by gonadal hormone exposure during early human development.

Infant and Adolescent Toy Play Preferences

For many, it is taken for granted that boys play with boys toys and girls play with girls toys, however, the causes of these outcomes has been heavily investigated. Studies have demonstrated that clear sex differences exist between infants and adolescent children when it comes to toy selection. On average, when given the choice, boys spend significantly more time playing with male-typed toys such as wheeled vehicles, trains and planes than female-typed toys, with the reverse being true for girls. While there are social components and influences to toy selection as the child develops, what is most striking is the strong link between this behavior and early prenatal androgen exposures.

While it would be unethical to conduct a hormonal manipulation studies on humans, a condition known as congenital adrenal hyperplasia or CAH provides a natural model to study the effects of elevated prenatal androgen exposure on XX and XY genetic backgrounds. Although CAH affects both males and females, sex differences have been most extensively studied in CAH females. CAH results from a mutation in key enzymes required for proper cortisol synthesis, as a result of these mutations, precursors to cortisol are shuttled into the androgen synthesis pathway within the adrenal glands. Due to the overproduction of androgen by the adrenal glands in XX CAH girls, they are born with a wide array of phenotypes. These outcomes range from the simple virilizing (SV) form, causing a more subtle masculinization of the genitals in addition to androgen exposure on the brain during development. The more severe and life-threatening form is the salt wasting (SW) type of CAH, often resulting in a more pronounced masculinization of the genitals along with heavy androgen exposure on the brain. As we will discuss further, some of the reviewed psychological measures often correlate strongly with the type of CAH an individual has, meaning it can also correlate to the level of androgen exposure during development, as SW CAH typically is exposed to more androgen than those with SV CAH while in the womb. Individuals with what is known as nonclassical CAH (NC), experience late onset symptoms of the condition and are not typically exposed to excessive levels of testosterone during developmental periods (Bramble et al., 2017).

The vast majority of studies that have assessed androgen exposure during development and toy choice preferences have largely drawn conclusions from studies involving individuals with CAH. It has been shown that girls with CAH, on average choose

masculine boy's toys when given the chance at a higher frequency than control non-CAH girls. Additionally, girls with CAH tend to play with typical girls toys less than the control girls in most studies (Alexander and Hines, 2002; Hines, 2003; Pasterski et al., 2005). By designing studies focused on individuals with CAH has provided strong evidence indicating that prenatal androgen exposure can indeed influence individual's toy choice. Critics of this work would argue that these observed outcomes are more socially influenced than based on prenatal androgen exposures; interestingly, studies using infants have also demonstrated an androgen effect on toy/object preference. When 12, 18 and 24 month olds were assessed, it was still shown that a sex difference existed between girls and boys in regards to the types of toys and objects they were most visually focused to (Jadva et al., 2010). Using young children to demonstrate sex differences in toy choice preference only strengthens the notion that androgens in part, establish some of these differences adding to the biological component instead of a purely social aspect (Fig.1).

To further support the theory that androgens influence toy choice preference, several studies have been conducted in nonhuman primates to determine if sex differences are still detectable in regards to toy choice selection. A study conducted in 2002 using vervet monkeys found strikingly similar outcomes to those observed in human children. It was shown that male monkeys gravitated towards male-typical toys and female monkeys spent more time with the female-typical toy selections (Hines and Alexander, 2008). This was the first type of study using nonhuman primates which investigated innate factors, that is, testosterone exposure, and the subsequent downstream choice in sex typed toy selection. Similar outcomes were also observed in later studies using rhesus monkeys, where it was shown that male monkeys displayed stronger preferences for wheeled toys over plush toys, which were considered the more feminine choice by this particular group of researchers (Hassett et al., 2008).

Generally speaking, the studies that have assessed toy play preference between male and female children for the most part all detect a sex-difference in regards to the types of selections that each gender are drawn to. While toy play preferences can and do have strong social influences, such as parent encouragement or discouragement when a child plays with an object that would be considered cross-gendered, there appear to be other biological factors which contribute as well. Despite a social link, child toy preferences are not simply influenced by gender socialization alone, but as discussed also influenced by prenatal androgen exposures. Studies which have measured testosterone levels in children often make strong correlations between those levels and the outcomes

Fig. 1 General distribution of toy choice preferences observed for adolescent girls with CAH versus control-female and control-male populations.

in toy selection. Additionally, works focused on children with CAH and nonhuman primates provide some of the strongest data indicating that androgen exposure is indeed a factor that contributes to these observed sex-differences. Collectively, toy play preferences in children are clearly influenced by early prenatal androgen exposure on the brain, highlighting one of the better documented examples of some of the psychological effects that occur during mammalian sexual differentiation.

Cognitive Differences Influenced by Sexual Differentiation

When focusing on specific cognitive differences, there are many studies that have identified small to moderate sex-differences that exist between males and females of all ages. It has been confidently shown for the most part that males show superiority when tasked with finding solutions involving spatial ability. More specifically, when it comes to 3D mental rotation ability, males tend to outperform females; thereby generating the larger sex-difference identified within the category of spatial ability tests. Other small to moderate cognitive differences which males have shown an advantage include but are not limited to, geographic ability, targeting, mechanical ability/knowledge and navigation tasks. Females on the other hand show superiority in cognitive skills such as memory and tasks involving language and verbal fluency. Some controversy in the field exists when it comes to the cause and size of these identified sex differences (Voyer et al., 1995). It has also been shown that these cognitive abilities can be improved over time with practice such as targeting and geographical awareness. However, some of these sex-differences such as spatial ability are able to be detected at early postnatal time points. Like toy play, it appears that in utero factors such as androgen exposure contribute to establishing such differences between the sexes, with the strongest evidence again coming from studies involving individuals with CAH.

When assessing spatial abilities between girls with CAH versus their unaffected sisters, numerous studies have identified significant differences between the siblings. Girls with CAH on average outperform their unaffected sisters in measures such as mechanical knowledge, geography and 3D mental rotation abilities (Fig. 2A). Interestingly, when assessing males with CAH compared to unaffected brothers, an enhancement in spatial ability was not identified but rather a reduction (Fig. 2A) (Berenbaum et al., 2012; Hines et al., 2003). Some researchers have interpreted these unusual findings in males as possibly being influenced by other factors with the CAH condition and not androgens directly, as males often have more medical difficulties when affected with CAH. But these outcomes could also indicate that it is not just the exposure of androgen on the brain that is important for establishing sex-differences, but also the spatial, temporal and dosage of hormone during development. This enhancement of spatial abilities in girls with CAH is also likely influenced by their early interests such as toy play or their increased interests in male-typical hobbies

Fig. 2 The general trends observed for the influence on various cognitive and personality traits in control-females, control-males, CAH females and CAH males. (A) Aggression, (B) dominance, (C) tender-mindedness, (D) interest in infants and pets, (E) male-typed hobbies and (F) 3D mental rotation ability.

(Fig. 2B) and activities like rough and tumble play; increasing the chance for improving on these male typical cognitive strengths (Mathews et al., 2009).

The evidence generated from research that has focused on males and females with CAH provide some of the strongest support for the role of androgens on generating spatial capacity and awareness within the human brain. While spatial abilities show one of the larger detectable differences, others have also detected variances between CAH girls and siblings on other personality and cognitive traits. It seems that androgens not only increase spatial ability, but can also increase physical aggression (Fig. 2C) and dominance (Fig. 2D) in girls with CAH versus appropriate control populations; and reducing such measures in CAH males (Mathews et al., 2009; Pasterski et al., 2007). Other smaller differences that have been identified also include, but are not limited to concluding that females with CAH show less interest in female typical traits such as being more tender-minded (Fig. 2E) and having curiosity in babies and pets (Fig. 2F). The effect of androgens on CAH males appears to be either reduction of male typical behavior or in some cases nonexistent. However many sex differences studied in CAH females suggest that prenatal androgens masculinize their behavior. As with toy play, there are social factors that add to increasing such sex-differences in cognitive ability. However, from the comprehensive studies conducted on children with CAH, it appears clear that androgens exposure during in utero development has an organizational effect which at least sets the stage for the establishment of these identified cognitive differences between the sexes. There have been studies with nonhuman mammals also linking prenatal or neonatal levels of gonadal hormones, especially testosterone, on behaviors that exhibit cognitive sex differences. Collectively, these studies strengthen the notion that hormones are important influencers of cognitive traits in humans as well as other mammals.

The Role of Androgen Exposure on Influencing Sexual Orientation

In regards to sex-differences between males and females, sexual orientation shows one of the largest measurable differences, as most males sexually prefer females, and most females sexually prefer males. This sex difference has been reported to have a d value or effect size equal to 6.0–7.0 (Meyer-Bahlburg et al., 2008). For general comparison, the effect size observed for differences in toy play preferences and reported cognitive differences typically fall below a d value of 2.0. The Kinsey scale is often used to quantitatively measure sexual orientation. On this six-point scale, individuals that fall within 0–1 are considered exclusively heterosexual and a score of 5–6 is defined as predominately/exclusively homosexual. While the vast majority of the population is heterosexual, it appears that females display a more variable and fluid sexual orientation pattern, whereas males typically are exclusively heterosexual or homosexual, with a smaller percentage falling into the bisexual range (Fig. 3A). The exact causes of nonheterosexual behavior have yet to be fully elucidated in humans. However, significant genetic, epigenetic and social/psychological works have drawn strong biological conclusions, indicating that sexual orientation is an inborn phenomenon and not a result of socialization (Bailey et al., 2016). As we will discuss further, there are many variable aspects to consider when measuring human sexual orientation, as societal, religious and familial components can affect the display of this human trait. As earlier mentioned, studies conducted on rodents have shown that gonadal hormonal manipulation during the critical period of development can alter downstream sexual behaviors. Specifically, if female rat fetuses are exposed to exogenous testosterone during prenatal development, when stimulated in adulthood with proper hormones, they display a masculinized/defeminized pattern of copulation. These results indicate in part, that androgen exposure on the female brain can alter sexual behavior and possible orientation in humans. Here we will discuss the evidence supporting the role of androgen exposure in affecting female sexual orientation, where again the largest supportive data has been generated from studying women with CAH.

Given that the expression of one's sexual behavior can be constrained by factors independent of biological predisposition, measuring sexual fantasies such as thoughts during masturbation and sexual night or day dreams (total imagery), tend to be more reliable indicators of sexual orientation. When assessing total imagery in women with CAH it has been shown that nonheterosexual outcomes are detected at higher rates depending on the severity of the condition. So by this, individuals with the salt wasting (SW) type of CAH show the most nonheterosexual total imagery outcomes, followed by those with the simple virilizing (SV) type and lastly by women with the nonclassical (NC) category of CAH (Fig. 3B). Studies have also assessed the level of cross-gender fantasies in women with CAH during intercourse or masturbation, as rates of gender dysphoria have been observed at higher rates in CAH women than seen in the general population. These measures have shown that those with the SW form show the highest levels of this cross-gender imagery during these acts, however this measure does not correlate with severity of disease as was observed for total imagery fantasies (Fig. 3C) (Hines, 2011; Meyer-Bahlburg et al., 2008).

When Kinsey score assessments are given to women with CAH, similar trends are observed; individuals having the SW CAH report higher scores (nonheterosexual). These scores decrease as disease severity decreases; all three types of CAH report higher Kinsey scores than control females (Fig. 3D). Using Kinsey score measures it has also been shown that women with the most severe form of the disease report higher scores on assessments measuring various behaviors such as masturbation erotica, masturbation fantasies and attraction (Fig. 3E). However, despite having higher nonheterosexual scores than control population on multiple measures, this does not always necessarily translate to actual sexual partners. The vast majority of individuals with CAH are heterosexual, however, there is a significant increase in the actual number of same sex partners that women with SW CAH have. Women with both SV and NC forms of CAH also display higher rates of having same sex partners when compared to appropriate control females (Fig. 3F) (Meyer-Bahlburg et al., 2008).

Studies conducted on individuals with CAH have strengthened the notion that prenatal androgen exposure can cause increases in masculinized sexual behavior, specifically on a XX genetic background. As mentioned, most women affected with this condition

Fig. 3 General trends and distributions observed within the general population and between individuals with varying types of CAH, including nonclassical, simple virilizing and those with the salt wasting form. (A) General male and female distribution of Kinsey scores observed in general population samples. (B) General observations for total imagery in individuals with CAH. (C) General observations for cross gender imagery in individuals with CAH. (D) Overall reported Kinsey scores for the various types of CAH. tend to not display nonheterosexual behaviors or fantasies; however, the majority of studies conducted on such questions continually find significant differences when compared to control females. As with other androgenic influences on the brain, some argue that the results of increased nonheterosexual behavior in women with CAH are more from a result of social components over biological explanations (Jordan-Young, 2012). While there may be measures that have social components involved, the majority of the scientific community that have assessed sexual behavior in cases of CAH more frequently than not indicate that prenatal androgen exposure does in fact alter sexual behaviors and fantasies in women.

Concluding Remarks

Since the early 1900s researchers have been expanding the understanding of how gonadal hormones masculinize the internal and external reproductive organs of mammals. In 1907, Frank Lillie determined that a freemartin or an infertile female cow with masculinized genitals was a result of sharing a womb with a male twin fetus (Capel and Coveney, 2004). He was successful in determining that a substance secreted by the male twin fetus was the cause for this masculinization, that substance was testosterone. Years later, a highly skilled French surgeon named Alfred Jost was able to expand on the understanding of how testicular secretions were able to alter reproductive organs. Not only did he show that testosterone caused genital masculinization, but he also identified a secondary hormone that was secreted by the testes which is now known as anti-Müllerian hormone or AMH (Jost, 1948). These key findings really opened the field of understanding sexual-differentiation of the mammalian body, specifically the hormonal effects on genital formation. However, with the 1959 publication by Phoenix et al. it became clear that gonadal hormones not only affected the body, but sexual differentiation could also affect the brain and most interestingly, sexual behavior as well (Phoenix et al., 1959).

After the establishment that gonadal hormones act via activational or organizational pathways, downstream rodent studies sought to identify the details and changes that were occurring within the mammalian brain during and post-testosterone exposure. A large number of studies have shown that organizational effects of testosterone on the brain are robust and affect anatomic structures, neural circuitry, sexual behaviors and other cognitive abilities. Despite extensive research on hormonal organization of the brain, the exact molecular mechanisms of this process largely remain elusive. More recent literature is now suggesting that the enduring effects of gonadal hormonal exposure on the brain are modulated in part by chromosomal sex but even more so by epigenetic mechanisms, such as histone modifications and DNA methylation. In fact, a recent publication determined that by altering the DNA methylation machinery and levels of methylation in specific regions of the brain, the downstream behavior of rodents was able to be modified, even post in utero organization (Nugent et al., 2015). Our research group also recently uncovered that sex-differences exist in the early cells of the developing brain, neural stem cells, and that these cells display different responses when exposed to testosterone (Bramble et al., 2016). Collectively, over the past decade significant studies have identified the power of sexual-differentiation on the brain, however much work is still required to fully elucidate the mechanism behind this interesting developmental phenomenon.

While rodent studies are interesting and have provided the foundation for our understanding of sexual differentiation of the rodent brain, a far more limited understanding of sexual differentiation of the human brain still exists. It is through studies of individuals with disorders of sex development (DSD), most specifically CAH that researchers have been able to better understand the downstream psychological effects of sexual-differentiation (Bramble et al., 2017). As reviewed here, it is apparent that gonadal hormone exposure during in utero human development can alter preferences for specific objects, sexual behavior and other cognitive differences.

It has been shown by studying individuals with CAH and nonhuman primates that androgen exposures on the developing brain influence the downstream preference for toy choice. While socialization can affect this outcome, as we have discussed, these differences begin to appear as early as 12 months, indicating that these effects are inborn and largely influenced by testosterone. The studies conducted with CAH men and women have also expanded the understanding of some of the roots for establishing cognitive differences between males and females. These findings for the most part, indicate that testosterone enhances specific male-typical cognitive strengths when female fetuses are exposed to high levels of testosterone during development. In addition to androgen exposure setting the stage for toy preference and specific cognitive abilities, it also becomes apparent from studies in CAH women that it also affects sexual behavior and may increase the rates of nonheterosexual orientation in females.

In summary, from the extensive rodent studies that have been conducted and some of the human research reviewed here, it is very convincing that testosterone exposure on the brain can elicit significant outcomes and largely contribute to the establishment of psychological effects of sexual differentiation.

Sex Ratio at Birth

Victor Grech, University of Malta Medical School, Msida, Malta
William H James, University College London, London, United Kingdom

© 2018 Elsevier Inc. All rights reserved.

Introduction

The human sex ratio (males:females) varies depending on when it is measured. The primary sex ratio is that at fertilization. The secondary sex ratio is that at birth. The tertiary sex ratio is that of the sexually mature members of any particular population and the quaternary ratio is that of the surviving populace at post-reproductive age. This article will deal with the secondary sex ratio, which will henceforth be referred to as M/T (male divided by total births). In humans, male live births slightly exceed female live births, such that this ratio approximates 0.515 (515 male:485 female births) (James, 2015).

The causes for the observed variations of M/T may be classified as “ultimate” or “proximate.” Ultimate causes are those hypothesized to be adaptive that is, to maximize reproductive success, and to therefore have arisen via evolution and natural selection. Proximate causes are those closest to an event and therefore immediately responsible for the observed results. Proximate causes may serve ultimate causes but not all observed proximate causes are adaptive. A veritable plethora of influences have been shown to affect M/T, and this article will provide an outline. Where events are mentioned or reported, this implies that such findings are statistically significant at or below the 5% level (i.e. $P \leq 0.05$).

Historical Notes

The theory and study of M/T has an old and interesting history. In ancient times, it was widely believed that an infant's gender was determined by the degree of heat that a man's ejaculate was exposed to during insemination, adhering to the classical notion of the four elements that comprise nature: earth, air, fire, and water. Laterality was also deemed important by some of the ancient philosophers in that as the male was thought to be superior to the female, so was the right side deemed superior to the left. Hence, by conflating the two theories, it was concluded that the right side/testicle is hotter and associated with the engenderment of males, and the cooler left side was associated with the engenderment of females. Theories continued to multiply with little actual science until the scholarly, post-Enlightenment world of the 18th century began to be intrigued by the regularity and occasional variations in M/T. This investigators included physico-theologians such as John Arbuthnot and Johann Peter Süssmilch, mathematicians such as Nicolas de Condorcet, Pierre-Simon Laplace and Denis Poisson, agronomists such as Charles Gilbert de Morel-Vindé and Charles Girou de Buzareingues, physiologists such as Johann Daniel Hofacker and organizers of statistical observations such as Joseph Fourier and Adolphe Quetelet (Brian and Jaisson, 2007).

The accurate collection of birth data from London allowed John Graunt (1620–74) to publish the first ever descriptive analysis of M/T data. John Arbuthnot (1667–1735) extended this dataset to publish the first ever statistical test based on the symmetric binomial distribution, demonstrating that the male excess was statistically significant, that is, highly unlikely to be due to chance alone (Brian and Jaisson, 2007). Charles Darwin (1809–82) was initially intrigued by the almost precisely equal allocation of male and female births, but later decided “that the whole problem is so intricate that it is safer to leave its solution for the future” (Darwin, 1874).

The explanation for the almost equal sex ratio pertains to the theory of games, in that were male births less common than female, a male would have better mating prospects and would sire more offspring. Thus, parents genetically disposed to produce males would have more offspring and this tendency would spread within the community, increasing male births, such that this advantage disappears when an M/F of 0.5 is reached. The converse would apply were there a dearth of females. This is known as Fisher's principle (Brian and Jaisson, 2007).

Stress: Hormonal Theory of Termination (HTT)

Since the human biological sex does not alter post-conceptually, M/T depends on two factors: the primary sex ratio and its alteration by sex-selective embryonic and/or fetal death (miscarriage and/or stillbirth). Stress decreases M/T and this was strikingly demonstrated following the 9/11/2001 attacks on the United States (US) by Ralph Catalano and colleagues who showed that the terrorist attacks were associated with a decrease in M/T 4 months later (Catalano et al., 2006). The phenomenon was shown to be due to an excess of male fetal loss in pregnancy (Bruckner et al., 2010). The same group has shown other analogous situations that reduced M/T, and these include mass layoffs and the Great East Japan Earthquake in 2011 (as reviewed in James and Grech, 2017).

Ambient temperature is a simple stressor to test and it has been shown that a 1°C increase in annual temperature (as a consequence of a milder winter) predicts one more male than expected for every thousand females born in a given year. Furthermore, males from cold-stressed cohorts who have experienced cold weather in utero culling have, on average, longer life expectancies. This has been calculated as an average decrease in male life-span by 14 days per 1°C increase from one year to the next among those who survived to one year of age (Catalano et al., 2008).

Others have identified a wide spectrum of human stressors associated with subsequent low M/T and these include the sovereignty referendums in Canada, parliamentary elections in Malta, the 2007 recession in the U.S., and maternal occupational stress.

Even relatively mundane events may transiently lower M/T, and these included the death of Princess Diana in 1997 in the UK. Lastly, pregnant Muslim women who observe the fast of Ramadan in early pregnancy have a low M/T (as reviewed in [James and Grech, 2017](#)). A common factor is that with all such acute events, the dip witnessed is transient, occurring approximately 4–5 months after the exogenous stressor ([Catalano et al., 2006](#)).

Such dips are also very sharp and dramatic. To put them in context, the perinatal mortality rate (number of stillbirths and deaths in the first week of life/1000 live births) is universally considered a major marker in the assessment of the quality of health care delivery. This is expected to be under 7/1000 for developed countries. The transient M/T dips observed match and sometimes even double or triple this value, making this not only an important Public Health issue but also a potential and inexpensive metric to objectively assess the effects of population stressors ([Grech, 2015d](#)).

The proximate cause for these effects is the Hormonal Theory of Termination (HTT) by William H. James which can be summarized by the proposal that M/T is positively correlated with R , where R is a function of the form

$$R = \frac{(T + E)}{(G + P)}$$

wherein T , E , G , and P are sex-standardized levels of testosterone, estrogen, gonadotrophins and progesterone of both parents at conception ([James, 2004](#)). Indeed, a major cause of miscarriage is known to be a high level of stress-induced maternal adrenal androgens ([James, 2015](#)). Indirect support for HTT comes from the Baron-Cohen hypothesis which proposes autism as a form of extreme maleness which may be induced by high maternal androgen levels in a condition that is far commoner in males than in females ([Baron-Cohen, 2002](#); [James, 2012](#)).

Relevance to Trivers-Willard Hypothesis (TWH)

The HTT is further strengthened by the fact that all such stress-related variation would be in conformity with the Trivers-Willard hypothesis (TWH). This maintains that evolution should have favored parents with the ability to influence M/F according to conditions surrounding conception and during pregnancy. This is because in polygynous species, a robust son who is conceived under favorable environmental conditions has greater reproductive opportunities than an equivalent daughter who is constrained by pregnancy and lactation. Contrariwise, under adverse conditions, a male fetus (which requires greater resources in order to be carried to term) will be less likely to survive pregnancy. If he does, such a frail male may not survive to reproductive age, and if so, would compete poorly with more robust males for mating privileges. However, a frail female is likelier to survive and reproduce. Hence, under unfavorable conditions, the parental passage of genes is favored if fewer males are produced through the culling of weaker males ([Trivers and Willard, 1973](#)).

Thus, HTT with maternal-stress-induced spontaneous abortion of small, frail male fetuses is a proximate cause, serving the ultimate TWH cause dictated by evolution.

Socioeconomic Status

Many studies have shown that different races have different M/T. This may be due to innate physiological differences or to other factors, which may be environmental or iatrogenic. In the US, M/T was Asian or Pacific Islander > White > American Indian or Alaska Native > Black or African American. M/T declines in association with surrogates of socioeconomic status, presumably due to higher stress levels. The lower baseline M/T of Indian or Alaska Native and Black and African American is equivalent to a constant loss of 3.5–4/1000 male births when compared to White M/T. Race is the most significant variable associated with wealth inequality in this country and may be partially responsible ([Grech, 2017a](#)). The high Asian M/T will be discussed later.

Radiation Elevates M/T

Radiation is the only known toxin which elevates M/T by destroying female in excess of male fetuses, for reasons unknown. This has been shown to occur in proximity to nuclear reactors ([Scherb and Voigt, 2007](#)), and after the meltdown of the Windscale (Sellafield) and Chernobyl reactors in 1957 and 1986 respectively ([Grech, 2014a,b](#)) and in association with the nuclear bomb tests leading up to the Partial Nuclear Test Ban Treaty in 1963 ([Grech, 2015a](#)). Indeed, it has been shown M/T increases 0.0036 (over the approximately 0.515 baseline value) when the normal average background radiation dose rate of 0.1141 $\mu\text{Sv/h}$ is doubled to 0.2282 $\mu\text{Sv/h}$ ([Scherb and Voigt, 2007](#)).

Time of Conception Within the Menstrual Cycle (TWC)

TWC states that the regression of sex ratio (M/T: proportion male) on time of conception within the human menstrual cycle is U-shaped. This is relevant as increased coital activity increases the likelihood of the odds of conception early in the menstrual cycle, thereby skewing the odds toward males, elevating M/T. Statistically significant evidence for TWC comes from a meta-analysis of

births (James, 2008). Indirect evidence also abounds, including the finding that during the Great Wars, M/T rose in belligerent countries. In times of war, an adult sex ratio imbalance prevails, with more males being away from their homes, and soldiers were granted short periods of leave in order to return home. This has been claimed to result in sexual excesses, “actions [that] were viewed as understandable responses to the Frauenuberschuss,” the excess supply of women (Moeller, 1993). Such increased coital activity may have caused the M/T elevations.

This would also explain other reports of high M/T 9 months after occasions of public elation such as the reported high M/T in South Africa 9 months after the 2010 World Cup there and the reported high M/T in the UK after the birth of Prince William in 1982. High coital rates might also explain the reported high fertility and M/T in Hong Kong in the auspicious Dragon years of 1976, 1988, and 2000. Lastly, the powerful decline in coital rates with duration of marriage would persuasively explain the decline in M/T of first births with the duration of time between marriage and birth (James and Grech, 2017).

Temporal and Geographical M/T Variation

M/T may exhibit seasonal variation, typically peaking as summer approaches. This was clearly demonstrated for example in the US with a significant peak in June that exhibited a degree of racial variation (Grech and Borg, 2015).

An overall decreasing trend in M/T is present in Europe and North America. This is offset by a rise in M/T in Asia that will be discussed later (Grech, 2017).

A latitude gradient in M/T is evident, with more males being born in southern, warmer latitudes in Europe. The converse occurs in North America, with more males born in northern latitudes (Grech, 2017).

Gendercide and Faminelect

Gendercide and faminelect (the deliberate infliction of lower standards of care of female neonates, infants and children, simply because of their gender) is rampant, especially in Asia, and has resulted in stark demographic sex imbalances in many countries. This paradigm is impelled by social, cultural, political, and economic factors which are predominantly caused by the tendency for patrilineal inheritance in patriarchal societies, coupled with a reliance on male children to provide economic support indefinitely. For this reason, due to the patriarchal nature of most societies, male offspring preference is far commoner than female preference.

In Asia, this is reinforced by the Confucian tradition that is characterized by strong son preference and female subordination. Gender-selective abortion favors males and this is the likeliest explanation for the high M/F noted in Asian or Pacific Islander births in the US (Grech, 2017a).

This is further reinforced by a US birth order analysis by race which showed that M/T decreased with increasing sibling order for all races except for Asian or Pacific Islander births, where M/T rose progressively to 3rd order births then fell. The implication is that group may be systematically implementing gendercide. Thus, the potential effects of increasing maternal age and/or decreasing coital rates with time to decrease M/T are not only excluded in this race, but go contrary to the findings of this particular study insofar as Asian or Pacific Islander births also had the oldest mean maternal ages for all birth orders (Grech, 2017b).

While the lower baseline M/T of Indian or Alaska Native and Black and African American is equivalent to a constant reduction of 3.5–4/1000 male births when compared to White M/T, the Asian or Pacific Islander strategy is equivalent to a constant loss of 3.5 females fetuses per 1000 live births when compared to Whites (Grech, 2017b).

The likelihood that gendercide is routinely used in these cultures is reinforced by the observation that in Asian countries where education levels rise, M/T drops to values that closely approach those of other races. This was famously observed in South Korea where M/T had peaked at 0.538 in 1990, but dropped to 0.513 by 2013 due to education campaigns, the first Asian country to reverse this trend (Chung and Gupta, 2007).

It is estimated that the number of missing females has reached 126 million in 2010, and this is expected to peak at 150 million in 2035. The annual number of newly missing females is expected to exceed 3 million every year until 2050 (Bongaarts and Guilmoto, 2015).

Faminelect also kills. This may commence antenatally and continue antenatally. For example, in some cultures, when it is known that the fetus is female, failure to attend antenatal clinics and take the tetanus vaccine leads to excess female neonatal mortality. In these cultures, female children may have poorer vaccine uptake and poorer hospital attendances for acute illnesses, with increased morbidity and mortality. Indeed in South and East Asia, there is higher female under-5 mortality compared to males, in stark contrast to the rest of the world (Grech, 2015c).

Women in such countries may experience tremendous social pressure to produce sons, becoming repeatedly pregnant until they do so, since failure may incur violence, rejection or even death (Grech, 2015c).

Globally

A United Nations dataset divided regions into more developed, less developed countries, and least developed countries (as defined by the UN General Assembly). A temporal M/T review showed that in more developed countries, M/T was initially stable at 0.53 up

to 1979, then fell to 0.525. The reason/s for this decline are uncertain but may be due to the trend for delayed pregnancies in educated women with increasing maternal age and possibly decreased coital rates, as intimated above.

In less developed countries (and this group includes Asia), M/T was initially stable at 0.53, then rose after 1984 (presumably after the introduction of ultrasonography and access to this as well as other advanced reproductive techniques as an antenatal sex determining strategy) to 0.545 with a rise in male births and a fall in female births. This further confirms widespread femicide.

The least developed countries exhibited a stable and lowest M/T of 0.52 and this may be due to chronic stress (Grech, 2015b).

Conclusion

While acute events may transiently decrease M/T when related to stress, or chronically decrease M/T in the presence of chronic stress, M/T may also occasionally witness a sharp rise in relation to events that lead to elation and presumably to increased coital activity.

However, the effects of all these pale into insignificance when compared to two man-made effects: radiation exposure, and gendercide and femineglect. These influences have drastically increased M/T, wreaking demographic havoc. The latter influences have most taken effect in Asia, resulting in extensive demographic masculinisation. The large number of missing women has led to speculation that these regions will experience increased levels of antisocial behavior and outright violence. Such individuals are likely to be drawn toward military organizations, potentially threatening global security, particularly since this imbalance is occurring in a global political hotspot (Grech, 2015c).

There are few positive outcomes in these scenarios and these are a reduction in the number of unwanted children and a self-limiting situation since any gender imbalance will lead to a reduction in birth rates. In addition, as the number of girls decreases, their social status should increase due to their rarity, leading to a decline in son preference. Furthermore if, due to scarcity, a significant proportion of men marry older women, there should be fewer single, lonely individuals in old age since women have a greater life expectancy than men. And finally, education may simply eventually obliterate offspring sex bias (Grech, 2015c).

Acknowledgments

WHJ is indebted to Professor Sir David Spiegelhalter FRS (Laboratory of Statistics, University of Cambridge) and to Professor Robert Trivers (Rutgers University) for their generous assessments of his hypothesizing on sex ratio at birth. He is also grateful to Professor Ralph Catalano (Department of Public Health, University of California at Berkeley) and to Professor Andrew Pomiankowski (University College London) for encouragement and advice.

Sexual Attractants

Introduction

Sexual selection occurs when individuals compete to fertilize the gametes of the opposite sex and operates at precopulatory, copulatory, and postcopulatory levels (Kokko et al., 2003). At the precopulatory level, mate choice between members of the opposite sex (i.e., intersexual selection) and same-sex competition (i.e., intrasexual selection) are the two principle mechanisms of sexual selection. Intersexual selection can shape the evolution of striking ornaments that enhance sexual attractiveness, while intrasexual selection can result in greater access to mates via resource acquisition or directly from winning fights (Kokko et al., 2003). This entry takes a comparative approach and discusses how these mechanisms have imposed on the evolution of visually conspicuous secondary sexual traits in humans.

Evolutionary research into human mate choice proposes that preferences were shaped during human ancestry to priorities morphology reflecting health, competitive ability and parental investment (reviewed in Grammer et al., 2003). A study among 37 diverse cultures revealed that women preferred a partner older than themselves with high earning potential, whereas men stated stronger preferences for youthfulness and physical attractiveness (reviewed in Grammer et al., 2003). Similar findings were reported among the Hadza hunter-gathers of Tanzania, where having a good character, foraging ability and physical attractiveness were the most nominated traits in women and men's ideal partners (reviewed in Dixon, 2012). Sex differences in body composition, skeletal structure, and stature are among several potential targets of intersexual and intrasexual selection during the course of human evolution. The purpose of this brief review is to highlight how sexual selection may have acted on some of these characters in women and men.

Sexual Attractants in Women

Unlike the nonhuman primates, where body mass is markedly sexually dimorphic, in humans sex differences in body composition are more pronounced than overall body size (Dixon, 2012). Women have more body fat than men, which is deposited around the hips, buttocks, and thighs (Singh et al., 2010). Body composition and shape can be measured using the waist-to-hip ratio (WHR), which takes the distance around the waist and divides it by the distance around the hips and buttocks. Premenopausal women from western populations typically have lower WHRs than men ranging from 0.67 to 0.8, while men's WHRs range from 0.85 to 0.95 (Singh et al., 2010). In women, a WHR of around 0.7 and a more "hourglass" body shape is associated with levels of body fat required for the onset of menarche, maintaining regular ovulatory cycles, and hormones associated with fertility (Singh et al., 2010). Fat in the thighs and buttocks is mobilized during pregnancy to support fetal growth, particularly during the third trimester for neural development (Singh et al., 2010). WHRs also become less hourglass with successive pregnancies and as women approach menopause (Singh et al., 2010).

Men's preferences for low WHRs in women may reflect sexual selection for mates who are younger with potentially higher fertility (reviewed in Brooks et al., 2015). Initial research, which was limited to western populations, supported the hypothesis that a low WHR of 0.7 was most attractive to men (reviewed in Brooks et al., 2015). However, subsequent cross-cultural research among small-scale subsistence societies revealed men preferred more masculine WHRs of 0.8–0.9 in women (reviewed in Brooks et al., 2015). Part of this variation was due to not accounting for body mass index (BMI) in the stimulus employed in many of these studies, as men from small-scale societies tended to prefer more corpulent physiques in women (Brooks et al., 2015). Subsequent cross-cultural research that controlled for BMI reported that men prefer low WHRs across a diverse range of traditional small-scale and industrialized societies (Singh et al., 2010). In the context of long-term reproductive processes, a healthy body fat distribution and body weight in women may provide men with cues of youth and fertility that guides their mate choice decisions.

In female nonhuman primates, breast enlargement only occurs during pregnancy and lactation due to milk production (Dixon, 2012). In women, breast development begins during adolescence and continues into young adulthood due to the deposition of stromal and adipose tissue around the mammary glands (reviewed in Dixon et al., 2015). Breast size is unrelated to the ability to produce or store milk. Instead, women with larger breasts have higher levels of estradiol and hence higher potential fertility (Jasienska et al., 2004) and breast fat provides energy reserves that supports lactation (reviewed in Dixon et al., 2015). Like body shape, breast morphology changes following pregnancies and over the lifespan, potentially providing a visual cue of women's sexual maturity, fertility, and maternal investment (reviewed in Dixon et al., 2015). Indeed, men rate images of larger breasts as looking sexually mature, reproductively healthy, and more nurturing as potential mothers (Dixon et al., 2015). However, men's preferences for breast size vary cross-culturally, so that among remote communities in the Highlands of Papua New Guinea, Samoa, Cameroon, and Namibia, men tend to prefer larger breasts than men from Western industrialized cultures like New Zealand and the Czech Republic (Dixon et al., 2011; Havlíček et al., 2017). While the cause for these cross-cultural differences are unknown, they may reflect preferences for greater fat reserves under conditions of nutritional scarcity.

Hormones associated with fertility also influence women's facial attractiveness to men. Female-typical "feminine" facial traits, such as large eyes, a round forehead and small chin are associated with higher levels of estradiol (reviewed in Grammer et al., 2003).

Cross-cultural research among 28 countries revealed that men prefer feminine facial features over more masculinized features (Markinkowska et al., 2014). Higher estradiol is also associated with subtle aspects of women's skin complexion that enhance attractiveness to men (reviewed in Smith et al., 2012). One study also found that facial femininity was positively correlated with estradiol and women's desire to invest as mothers (Smith et al., 2012). Taken together, hormones influence women's facial and bodily attractiveness to men in ways that may reflect sexual selection shaping traits associated with youth, fertility, and maternal investment.

Sexual Attractants in Men

Androgens underpin the expression of male-typical secondary sexual traits in men. During adolescent development, testosterone drives sexual dimorphism in height, musculature, facial shape (i.e., a defined jawline, deeply set eyes, a pronounced brow ridge and a robust midface, beardedness) and body hair. Owing to their reliance on androgens as men enter reproductive maturity, when competition to attract mates is pronounced, male secondary sexual characters are suggested to have been shaped by sexual selection via intersexual and intrasexual selection (Puts, 2010; Dixon, 2012).

In comparison to nonhuman primates, sexual size dimorphism in humans is not pronounced and men are only slightly larger than women (Dixon, 2012). However, muscularity is markedly sexually dimorphic, with men having 61% more muscle than women (Puts, 2010). Men's musculature is distributed around the shoulders and upper back, giving the body an overall v-shaped composition (Dixon et al., 2014). Muscularity is associated with physical strength, aggressiveness and competitive ability, health and disease resistance (Puts, 2010). Women judge a more muscular physique in men as most sexually attractive across cultures (Dixon, 2012) and muscularity is associated with men's mating success (Puts, 2010), suggesting that mate preferences for muscularity are associated with actual mate choices. Likewise, men are typically taller than women and male height is positively associated with men's reproductive success and formidability in male-male competition (Stulp and Barrett, 2016). One study employing multivariate approaches to measuring women's preferences for men's physique reported that muscularity accounted for 80% of the variation in attractiveness judgments and height explained a further 10% (Mautz et al., 2013). Thus, muscularity and height appear to play a strong role in both intersexual mate choice and intrasex competition.

Male primates express a wide diversity of visually conspicuous ornaments, badges of status and weaponry. Some of the most iconic examples include fleshy traits like "cheek flanges" in the male orangutan (*Pongo* spp.), the enlarged nose in male proboscis monkeys (*Nasalis larvatus*), and the large size of the upper-lip in male golden snub-nosed monkeys (*Rhinopithecus roxellana*). Other examples include colorful characters like the red triangle on the chests of male geladas (*Theropithecus gelada*) and the violet fattened rump of alpha male mandrills (*Mandrillus sphinx*). Finally, male primates have conspicuous hairy appendages like the silvery capes of hair that cover the bodies of male hamadryas baboons (*Papio hamadryas*) and facial hair in orangu-tans (*Pongo pygmaeus*; Fig. 1). In the absence of a preserved fossil record of cutaneous characters among the direct ancestors to modern humans, comparative research across the anthropoids offers insights into the selective pressures shaping sexually dimorphic traits (Dixon, 2012).

If these ornaments were sexually selected by female choice, male-male competition, or a combination of the two mechanisms, one would predict that their expression would vary due to the prevailing mating systems (Dixon, 2012). Quantitative research including all male ornamentation, which included all hairy, fleshy, and colorful adornments, reported that primates with polygynous mating systems scored the highest for secondary sexual traits, followed by species with monogamous mating systems, with species with multimale multifemale mating systems scoring the lowest (Dixon, 2012). In these analyses, men were included first as a monogamous species and again as a polygynous species. Both those analyses revealed that polygynous primates scored highest for ornamentation (Dixon, 2012). A follow-up study reported a positive phylogenetic correlation across 154 primate species (including men) between ornamental dimorphism and social group size (Grueter et al., 2015). Ornamental dimorphism also differed according to social organizations, being greatest in males from species with multilevel social systems compared to species with less complex social systems (Grueter et al., 2015). As humans live in large social groups within complex multilevel social systems, men's degree of ornamental sexual dimorphism was similar to males from species of nonhuman primates with large social groups and multilevel social systems.

A large body of research has tested whether intersexual or intrasexual selection is the mechanism that best explains the persistence of men's secondary sexual traits (Dixon, 2012). Results of experiments testing whether masculine facial shape, beardedness, and body hair augment male attractiveness to women are mixed. In some cases, women's preferences are stronger for less masculine than more masculine looking men, while in others preferences are equivocal (reviewed in Dixon et al., 2017). In a similar vein, the majority of studies into women's preferences for male chest and trunk hair have revealed that hairless stimuli are judged as more attractive than hirsute stimuli (Dixon and Rantala, 2016). Studies quantifying women's preferences for men's beards are also mixed, so that beards are rated most attractive in some studies while clean-shaven faces were most attractive in others (reviewed in Dixon et al., 2017). Thus, masculine facial shape, beardedness, and body hair do not consistently enhance men's attractiveness to women.

Rather than augmenting attractiveness, men's secondary sexual traits may play a stronger role in intrasexual communication of dominance and social rank. Indeed, ornamentation in male primates may serve as badges of status and dominance rank that function during male-male agonistic interactions (Dixon, 2012). For instance, in male western gorillas (*Gorilla gorilla*) muscularity, body size, gray body hair and cranial adipose crests are incorporated into male-male displays (Dixon, 2012). Adipose crest size in males also positively predicts the number of females in one-male units and offspring survival (reviewed in Grueter et al., 2015). In geladas, the redness of the skin patch on the chest is brighter among males with larger harems, whereas bachelor and

Fig. 1 Examples of visually conspicuous secondary sexual traits in male anthropoids. Portraits in the upper row from left to right show Golden snub-nosed monkey (*Rhinopithecus roxellana*); Bornean orangutan (*Pongo pygmaeus*); Mandrill (*Mandrillus sphinx*). Portraits on the bottom row from left to right show Proboscis monkey (*Nasalis larvatus*); Red uakari (*Cacajao calvus*); Man (*Homo sapiens*). The drawings are used with permission from Alan F. Dixson.

secondary follower males have less pronounced coloration in their skin patches (Dixson, 2012). Red facial coloration in mandrills is most pronounced in dominant males and higher social rank (Dixson, 2015). However, mandrills also have strikingly large canines, which are employed during fights with other males often leading to severe injuries (Fig. 2; Dixson, 2015). Given that male–male competition occurs in almost all species of nonhuman primates and fights are costly, the rapid transmission of rank and status between males could serve to curtail the probability of an agonistic encounter leading to a costly fight.

This process may explain how sexual selection has shaped men's masculine secondary sexual traits. Thus, facial masculinity is associated with upper body strength, muscularity and fighting ability in men (Puts, 2010) and plays a strong role in intrasexual

Fig. 2 The portrait on the left is a male drill (*Mandrillus leucophaeus*) yawning and showing the greatly enlarged upper canines along with several secondary sexual traits including black facial skin and the enlarged paranasal swellings. The portrait on the right is a male mandrill (*Mandrillus sphinx*), also yawning and showing enlarged canines as in the drill. Note the skin covering the paranasal swellings consists of a series of bright blue ridges, whereas the central nasal strip and tip of the nose is red and the beard is yellow. These drawings are used with permission from Alan F. Dixson.

Fig. 3 Ratings of sexual attractiveness by 129 women for clean-shaven and bearded faces posing smiles (A); ratings of aggressiveness by 111 men for clean-shaven and bearded faces posing angry expressions (B); ratings of social dominance by 52 men for clean-shaven and bearded faces posing neutral expressions (C). Data are reproduced from Dixon B. J. and Vasey, P. L. (2012). Beards augment perceptions of men's aggressiveness, dominance and age, but not attractiveness. *Behavioral Ecology*, **23**, 481–490, and the stimuli are owned by Barnaby Dixon.

signaling of dominance and threat (Puts, 2010). Beards also consistently augment ratings of dominance in faces with neutral expressions and angry facial expressions (Dixon and Vasey, 2012; Fig. 3). While facial hair may not directly improve fighting ability, beards likely perform a role in enhancing threatening displays by amplifying masculine facial traits, such as the apparent size of the jaw, the overall length of the face and the effectiveness of threatening facial displays. Fig. 3 shows results of a study among men and women from New Zealand in which men judged angry faces with full beards as more aggressive than when clean-shaven. The same study also showed that men judged bearded faces as looking more dominant than clean-shaven faces, while women rated clean-shaven faces as most attractive (Dixon and Vasey, 2012; Fig. 3). This suggests that like many species of nonhuman primates, masculine facial traits play a role in communicating intrasexual threat.

Evolutionary biologists have long appreciated that the strength and direction of sexual selection by female choice varies with ecological factors (Kokko et al., 2003). Under ecological conditions wherein male–male competition can result in tangible direct benefits, such as protection and resources, females may have higher preferences for males displaying cues of intrasexual formidability (Wong and Candolin, 2005). Interestingly, women's preferences for facial masculinity are stronger in countries with lower healthcare, higher pathogen loads, greater income inequality and higher urban development (reviewed in Dixon et al., 2017). With regards facial hair, full beards are more common under economic conditions where disparity in incomes are greater, in cities with the largest populations, and in countries where women report the strongest preferences for beards (Dixon et al., 2017). These studies suggest that masculine traits and possibly men's decisions to remove or embellish a highly masculine signal through grooming vary due to social, ecological, and economic conditions in ways that are predicted by evolutionary theory.

Conclusion

Studies in human mate choice that employ evolutionary theories to uncover the targets of sexual selection have grown considerably in the past 25 years. Women's body fat distribution and secondary sexual traits may reflect youth, health, and fertility that explain their attractiveness to men. Men's secondary sexual traits appear to play a stronger role in enhancing male dominance to other males rather than aesthetical sexual attractiveness. Women's preferences for masculine traits appear to be stronger under environmental and economic conditions where survival is compromised, resources scarcer and their reproductive success may be enhanced by selecting a partner who can provide tangible benefits that aid their survival and that of their offspring.

Sexual Imprinting

Hans-Joachim Bischof, Bielefeld University, Bielefeld, Germany

© 2018 Elsevier Inc. All rights reserved.

Introduction

The phenomenon was already known for centuries, but it was [Lorenz, 1936](#) who coined the term imprinting (Prägung) based on his observations of young, artificially bred greylag geese. According to his observations, newly hatched geese immediately follow the first moving object they see (which in nature would be the mother or the siblings) and develop a strong attachment to it, even if, in case of an experiment, it is the animal caretaker who is retrieving the birds from the breeder. If the hatchlings thereafter are asked to choose between that object and another, they decide to follow that first seen object, a choice that persists as long as following behavior can be observed. Lorenz presumed that the attachment to the first object cannot be reversed after it has been established and thus named the underlying learning process “Nachlaufprägung,” named filial imprinting in the English literature. He further observed that the learned preference later in life also affected the mate choice of the birds: the sexually mature geese that were imprinted on the caretaker directed their courtship behavior to human beings instead of the mother. Lorenz called this phenomenon “sexual imprinting” because he presumed the preference for the “wrong” object would persist lifelong.

On the basis of his observations, Lorenz concluded that imprinting associates characteristics of an object with an innate behavior (in the case of sexual imprinting: the traits of the target for the innate courtship behavior). He listed four criteria that characterize imprinting: (1) Imprinting can take place only during a restricted period in the individual's life, the sensitive period; (2) it is irreversible, meaning that a learned preference cannot be forgotten; (3) only species specific, not individual characteristics are learned; (4) learning may be completed at a time where the appropriate behavior is not yet performed, for example, sexual imprinting occurs long before the birds are sexually mature.

These claims were, as usual at that time, based on anecdotal evidence and thus quite speculative. They initiated, however, intense discussion. A lot of research showed that Lorenz' intuition was generally good, but some of his claims had to be revised or even rejected. Over the last six or seven decades, many detailed studies of sexual imprinting contributed to a more complete picture of this important aspect of early development.

The Characteristics and Context of Sexual Imprinting

Early experience contributes to mate choice not only in geese, but also in many other birds, it was also shown for mammals, for several fish species, and even in invertebrates ([Verzijden et al., 2012](#)). For nonhuman primates, there is not much experimental evidence, but for humans, there is an impressive amount of literature dealing with the role of sexual imprinting for mate choice (see below). Such demonstration across the entire animal kingdom including humans already indicates that this type of learning is a universal phenomenon that plays an important role in the development of living beings.

However, the vast majority of studies on the characteristics and context of sexual imprinting have been performed in birds, and most of the avian studies used the Zebra finch (*Taeniopygia guttata castanotis*) as experimental animal which now can be seen as the standard model for sexual imprinting. [Immelmann \(1972\)](#) was the first to study sexual imprinting in detail with Zebra finches as model. He cross-fostered Zebra finches with another finch species, the Bengalese finch (*Lonchura striata*). Adult Zebra finch males, which were raised by Bengalese finches, preferred females of the foster species against those of their own species in a choice test. This indicated that the birds had learned the visual traits of their prospective mate while they were reared by the foster parents and excludes the existence of an innate template of their own species. By varying the duration of the cross fostering period, he found out that the sensitive period for sexual imprinting starts at the time of eye opening (about 6 days after hatch) and lasts up to about 30 days of age, most birds were imprinted from day 12 to day 14. He also showed that the cross-fostered males, if later housed together with a female of the own species, courted this female and even in some cases reared offspring. This result could on first sight indicate that imprinting is not as stable as Lorenz assumed. However, it turned out that the same cross-fostered males, when asked to choose, continued to prefer females of the foster species. Thus, sexual imprinting obviously established a stable preference for the foster species, but it was just a preference that determined the choice of the birds in most cases but could, depending on the actual circumstances, also be ignored (Review: [Bischof, 1994](#); [Ten Cate and Vos, 1999](#)).

By his experiments, Immelmann demonstrated that zebra finches learn the object for sexual behavior, and he presented experimental evidence supporting the first two of Lorenz' criteria: learning is restricted to a sensitive period, and the acquired preference is very stable. He also provided evidence for the notion of exclusive learning of species specific traits of that potential sexual partner (which would indicate that imprinting may be strongly restricted by genetic constraints), but later research indicated that it could not be excluded that individual traits also played a role, and imprinting was even possible on artificially added traits like colored rings or artificial crests (e.g., [Witte and Caspers, 2006](#), see also below).

These basic features were accepted by most researchers, but there was some dispute over other details. It was discussed, for example, whether both, males and females, acquire knowledge about a possible mate by early learning. For ducks, it was shown that only males learned the traits of their mates by imprinting, while females appeared to have an innate template of the appropriate

male mate. According to later experiments, however, females are also imprinted, but on traits of the father in contrast to the males that learned traits of the mother.

The statement of Lorenz that imprinting occurs at a time where the appropriate behavior is not developed was also discussed. Obviously, it is not true for filial imprinting where the following reaction is part of the process by which the bird learns the traits of the object to follow. For sexual imprinting, it appeared not to be logic to assume that young birds before reaching sexual maturity could learn about the object for their courtship behavior that was developing much later. Indeed, experiments demonstrated that the whole process of learning about a prospective sexual partner was more complicated. Young birds which were reared by Bengalese finches and then isolated until reaching sexual maturity, changed their preference to Zebra finches when the first female bird they were able to court was a Zebra finch female, while in the case of first courtship to a Bengalese finch, the preference for the Bengalese finches was preserved. The preference shown after the “first courtship” then could not be changed again. On the basis of these results, [Bischof \(1994\)](#) proposed a model which described imprinting as a two stage process: In an early acquisition period which resembled the sensitive period described by earlier work of Immelmann, the young birds acquire a searching image for a prospective sexual partner, and the “first courtship” towards an object which resembled the previously acquired searching image, after reaching adolescence was seen as a stabilization process which fixes this preference. In a later version, this model was modified in that the acquisition period could also be interpreted as some sort of filial imprinting where the Zebra finches are learning about social partners like parents, siblings, and other birds of the flock; the first courtship of these birds is then directed to members of that group, and thus the chance to imprint sexually on the own species is greatly enhanced ([Fig. 1](#)).

This interpretation, which I shall adopt here, is contradictory to Lorenz’ claim that learning of the mate’s traits occurs before sexual behavior is developed. Lorenz wanted to stress that imprinting might be a process different from associative learning because there was no obvious reinforcement; as shown above, however, later research mainly favored the associative learning idea instead of some process like exposure learning where the object traits are learned just by exposing it to the young animal. A good overview is provided by [Bolhuis \(1991\)](#).

Immelmann presumed that there was an “own species bias” because his experimental males imprinted more readily to the own species than to a foster species. This claim was quite strongly criticized because this could be seen as a genetically fixed bias, an idea which was not very popular in times of a behavioristically dominated learning research. However, such biases were found frequently also in later experiments, and with the acceptance that genetics and environmental both affect the development of brain structure and behavior, the own species bias in sexual imprinting became more and more accepted.

Most of the original experiments to define the bodily traits learned by sexual imprinting were done exclusively with visual cues. However, there is no doubt that others like acoustic or olfactory traits also contribute to the overall mental image of the sexual partner that is established by the imprinting process. Acoustic cues that have been shown to be stored in a two-stage process, also contribute to mate choice ([Bischof, 1997](#)). Likewise, recent research highlights a prominent role of olfactory cues, which are also stored in the course of a sensitive period, for individual recognition and thus also for mate choice ([Caspers et al., 2013](#)).

Neurobiological Correlates of Sexual Imprinting

[Bischof \(1983\)](#) recognized the strong similarity of the behavioral phenomena characterizing sexual imprinting with the development of binocularity of the visual system of cats and monkeys, one of the best investigated models of developmental plasticity. The two main criteria of sexual imprinting, a sensitive period and a remarkable stability of storage of the obtained information, also apply for the development of the wiring of the visual system, and there are other similarities even in details. It is probably more than pure speculation to assume that the physiological processes, which were described for the development of sensory systems, are also the basis for behavioral processes like sexual imprinting, and research on developmental brain plasticity could therefore guide physiological research on imprinting.

Fig. 1 (A) Male zebra finch (left) that was imprinted on a Bengalese finch and thus courting a Bengalese finch female. (B) A neuron found within one of the imprinting relevant forebrain areas. Dendritic spines are the tiny protrusions along the dendrites, which emanate from the cell body. Spine density (see [Fig. 3](#)) is measured along the length of the distal part of the dendrites.

Because the stabilization of the earlier acquired preference by the “first courtship” appeared to be the most important step in the imprinting process, Bischof and coworkers (review: Bischof, 2007) designed experiments to learn about the physiological basis of the stabilization process of sexual imprinting. By isolating the young birds from the (foster) parents after reaching independence and then exposing them to a female of the own or the foster species for a given period of time, it was possible to exactly adjust the time point at which the stabilization process occurred (see Figs. 2 and 3). Just 1 h exposure to a female, eliciting directed courtship behavior for the first time in the life of the young male, was sufficient to stabilize the previously acquired preference. Details of the physiological correlates of sexual imprinting could then be evaluated by comparing the brain status before and after confrontation with a female.

Among the brain areas that were active during the first exposure to a female, two higher order brain areas showed alterations, which strongly suggested that these areas were involved in the imprinting process. The exposure lead to a very rapid reduction of dendritic spines within the lateral nidopallium, an area which receives visual input from the avian tectofugal visual projection, and the medial nidopallium which is seen as to belong to the acoustic system and shows such reduction also in experiments on song learning. The reduction was permanent, subsequent isolation had no further effect on spine density. This irreversibility of the spine reduction indicated that it could represent the physiological basis of the also irreversible imprinting process: other areas activated by the first courtship event showed another pattern of change: the spine density increased with exposure to a female (much slower

Fig. 2 Sensitive periods in the zebra finch during normal development (upper panel) and experimentally altered (lower panel). P, probability of the occurrence of imprinting (arbitrary units). Upper panel: A social preference is installed around day 20 (blue shaded area), a sexual preference around day 100 (red shaded area). Lower Panel: By isolation, sexual imprinting can be restricted to a defined period of time (see also Fig. 3).

Fig. 3 Changes of dendritic spine density within an imprinting relevant brain area (“MNH”) during development. If the bird is growing up with other birds (“aviary”), the spine density, which indicates the number of connections between neurons, does not show strong variability. If the bird is isolated from day 40 to day 100, the spine density increased from day 70 on up to day 110 and then decreases until day 150 to the “aviary” level. It has been shown that during this time span sexual imprinting is possible (red square). If during this time the bird is exposed to a female, the spine density is dropping very quickly (“1. courtship”). Thereafter, no change of the installed preference is possible.

compared with the “imprinting areas”) and decreased to the value measured before the exposure when the birds were isolated thereafter. The experiment was interpreted as to show that by the stabilization process of sexual imprinting the previously redundant network within the two areas is shaped to a final less (non?) redundant state.

Other experiments demonstrated that isolation before the “first courtship” leads to an increase of spine density within the imprinting relevant areas higher than those observed in not isolated control birds. It was this excess of spines which was reduced when the birds were exposed to a female. This was interpreted as to show that imprinting under normal conditions may work in multiple steps so that the permanent generation of new spines was counteracted by an elimination of spines. It was also shown that the stabilization process of sexual imprinting is also restricted to a sensitive period, which begins at day 70 and ends at day 150. The onset of the sensitive period is characterized by a strong testosterone peak, and chemical castration prevents consolidation and spine density increase. The sensitive period may then be terminated by an increase of GABAergic inhibition. Alternatively, or in addition, it might be possible that, as has been shown for the development of the visual cortex and also for song learning, another variant of early learning which is very similar to sexual and filial imprinting, the development of the perineuronal net, a component of the extracellular matrix which serves to stabilize synaptic contacts, may have an influence on the closing of the sensitive period. Another, as yet not pursued path of investigation is the idea of epigenetic changes of the genome, which are induced under involvement of IEG’s and stress hormones. IEG expression and corticosterone enhancement are also involved in the stabilization period of imprinting, but as yet no evidence is available that would link epigenetic changes to the regulation of the sensitive period. If such changes were involved, it would be interesting to know whether these could be transferred to the next generation. If the effects of sexual imprinting were heritable, this would have immense consequences for our present view of the role of sexual imprinting for evolution.

The results on the neurobiological correlates of sexual imprinting strongly support the view presented above: there are impressive similarities between the physiological basis of brain development, for example that of binocular interaction within the visual cortex, and those of sexual imprinting. Within the visual system, experience from the external world is necessary to fine-tune a genetically prewired processing system. The same could be said from sexual imprinting and the physiological structures underlying it: a given behavioral system like that guiding mate choice may be prestructured to some degree, but it needs fine tuning by external information.

The idea that there may be a prestructured neuronal system, which leads to a predisposition, has also been confirmed in filial imprinting where research demonstrated for example perceptual biases from single traits like colors or preferences for animate objects. It has also been shown that such perceptual biases might be quite universal because they can be demonstrated in chicks as well as in humans (Di Giorgio et al., 2017). However, conceptual paths chosen in physiological research on filial imprinting were very different from those chosen by scientists working on sexual imprinting. Thus, although there is quite strong support for the notion that filial and sexual imprinting as like as song learning are very similar learning paradigms, nobody as yet has tried to reconcile the different concepts and to develop a unified theory of the physiological basis of early learning.

Evolutionary Aspects of Sexual Imprinting

Sexual selection and mate choice are of major importance for evolutionary theories since Darwin (1871). He proposed that the choosing sex (in most cases the female) is able to assess the reproductive investment and/or the reproductive potential of the candidate mate and chooses the best one on the basis of some phenotypic trait. Lots of theoretical essays thereafter refined aspects of Darwin’s ideas (Review: Jones and Ratterman, 2009), and besides the main assumption that mate choice is based on inherited preferences for certain traits, the role of sexual imprinting was also found to have strong impact on sexual selection. It can either enhance or reduce the effects of natural selection. Mathematical models, for example, suggest that learning preferably the parental traits (parental imprinting) can stabilize sexual selection on a specific phenotype, but also cause runaway sexual selection depending on the environmental conditions.

Sexual imprinting may also facilitate speciation by promotion of imprinting to species specific traits, or by the maintenance of sexual isolation between sister species when no postzygotic barrier exists, as shown in sticklebacks. Taken together, sexual imprinting may be one of the most important factors for speciation, even if one considers the many other influences on reproductive isolation. But it may not be possible at present to devise a common theory; instead one has to examine the influence of early learning on sexual selection on a case by case basis. (Review: Verzijden et al., 2012).

Sexual Imprinting in Humans

Psychologists traditionally saw human sexual preferences as to be genetically predetermined adaptations that serve to select the highest quality mate from a range of candidates. However, there are also attempts to find out whether the traits that allow judging the quality of a potential mate, may be learned instead of being inherited. In this context, sexual imprinting has been considered as the learning process that importantly affects mate choice in humans. Comparable with studies in birds, relations between parental traits and sexual or partner preferences have been shown in humans. Most of these studies demonstrated a relationship between partner preferences and traits of the opposite sex parents, similar to the findings in birds. Another important parallel between

animal and human studies was the demonstration of negative imprinting (the so-called Westermarck effect), by which an aversion instead of a preference for the imprinted trait is developed (review: Aronsson, 2011).

Aronsson also put forward the idea that the existence of sexual perversion like fetishism may be an effect of sexual imprinting on sexual preferences. She argues that the sexual preference for fetishes like underwear, socks, etc., may be comparable with sexual imprinting on artificial adornments as it has been shown in birds (e.g., Witte and Caspers, 2006). She also shows convincingly that sexual preferences in humans based on parental traits of parents can also include preferences for accessories like spectacles or behavioral traits like smoking.

There were also negative voices concerning the evidence proving sexual imprinting in humans. Rantala and Marcinkowska (2011) reviewed the current literature, criticized the concept at all and claimed that, due to inadequate methods, the effect of either positive or negative sexual imprinting on mate choice in humans is often more marginal than suggested by the original papers. Although this critique may be justified in some cases, there is enough robust evidence supporting the involvement of sexual imprinting in mate choice. That such an involvement is difficult to detect may probably be due to the fact that development and mate choice in humans is a phenomenon with multiple causes. Also, it has already been shown for Zebra finches that an acquired preference for a given trait or combination of traits does not mean that the birds are condemned to find exactly the ideal mate for courtship and reproduction; Immelmann demonstrated that a cross fostered Zebra finch male, if the preferred foster species is not available, also courts to females of the own species and eventually also raises offspring with one of these females. However, if later on given a choice between females of the foster and the own species, respectively, it will prefer the foster female and abandon the previous mate. If one assumes that human mate choice may be dependent on even more influences apart from imprinting (e.g., social, environmental, and economic ones) than that of Zebra finches, it is plausible to assume that the effects of sexual imprinting may be more strongly obscured and more difficult to prove.

FERTILIZATION

Sperm Capacitation

Brett Nixon and Elizabeth G Bromfield, The University of Newcastle, Callaghan, NSW, Australia; and Hunter Medical Research Institute, New Lambton Heights, NSW, Australia

© 2018 Elsevier Inc. All rights reserved.

Nomenclature

cAMP Cyclic adenosine monophosphate
 HCO_3^- Bicarbonate ion
 $[\text{Ca}^{2+}]_i$ Intracellular calcium concentration
PEBP1 Phosphatidylethanolamine binding protein 1
 pH_i Intracellular pH
PKA protein kinase A
SACY Soluble adenylyl cyclase, ADCY10
ROS Reactive oxygen species
ZP Zona pellucida

Introduction

Sperm capacitation represents the culmination of a spermatozoon's journey to functional maturity that begins within the testes (spermatogenesis) and continues as the cells are conveyed through the male (epididymal maturation) and female (capacitation) reproductive tracts. Since the coining of the term (Austin, 1952) and original description of capacitation by Chang (1951) and Austin (1951) more than half a century ago, significant advances have been made into our molecular understanding of its foundations (Aitken and Nixon, 2013; Gervasi and Visconti, 2016). This has led to an appreciation that capacitation encompasses a series of sophisticated physiological changes, designed to deliver a highly selected subpopulation of spermatozoa to the oocyte, which are capable of effectively engaging in the process of fertilization. Much of this knowledge is grounded in the ability to recapitulate capacitation in vitro using simple chemically defined media, the use of pharmacological interventions, and/or the analysis of loss of function transgenic mouse models. Here, we discuss how this information has transformed our understanding of the timing, mechanistic basis and biological significance of capacitation.

Timing of In Vivo Capacitation

Upon ejaculation, millions of spermatozoa are deposited into the female reproductive tract and tasked with the purpose of locating and fertilizing an ovum. Notwithstanding the level of specialization that the spermatozoa have achieved in preparation for this task, they remain incapable of recognizing the oocyte or engaging in the complex cascade of cell–cell interactions that culminate in syngamy. Indeed, the pioneering work of Austin and Chang independently established that spermatozoa must spend a finite period of residence in the female reproductive tract before acquiring the ability to fertilize an ovum (Austin, 1951; Chang, 1951). Such findings led to the coining of the term capacitation and its original definition by Austin (1952), to include those physiological changes undergone by sperm while in the female reproductive tract that render them competent to penetrate the egg. In the ensuing decades since these seminal discoveries, the necessity for capacitation has held true across the spermatozoa of all studied eutherian mammals. Further, there is emerging evidence supporting the need for analogous, capacitation-like changes for the activation of spermatozoa during their ascent of the female reproductive system in phylogenetically distinct vertebrate species such as the prototheria (Nixon et al., 2016b) and reptiles (Nixon et al., 2016a).

In terms of the timing of capacitation, the original definition proposed by Austin broadly encompasses all events from the moment of insemination into the female reproductive tract through to sperm penetration of the oocyte vestments (Austin, 1952). Notably however, the rate at which sperm cells capacitate is carefully regulated by the changing environment of the female reproductive tract, such that they are delivered to the surface of the oocyte in a fully primed state, ready for fertilization. A key element of this strategy, and one that increases the likelihood of synchrony with ovulation, is the formation of a transient postinsemination sperm reservoir (Fig. 1). Thus, upon reaching the caudal isthmus and uterotubal junction region of the oviduct, spermatozoa establish intimate contact with the ciliated epithelium and thereafter enter a quiescent state (Suarez, 2016). This

Fig. 1 Phases of *in vivo* sperm capacitation. (1) At the moment of insemination spermatozoa enter the female reproductive tract in a noncapacitated state. (2) The capacitation cascade encompasses a hierarchy of biochemical and biophysical changes that are initiated as spermatozoa disperse from the seminal fluids and begin their ascent of the uterine cavity. These early phases of capacitation are characterized by the loss of decapacitation factors and sterols from the sperm surface. (3) Upon reaching the isthmic region of the Fallopian tubes, spermatozoa bind to the epithelial cells and in so doing, establish a transient storage reservoir in readiness for ovulation. (4) Upon receipt of an appropriate stimulus coincident with ovulation, spermatozoa experience a rapid change in their biochemistry characterized by an increase in reactive oxygen species (ROS) generation, intracellular cyclic adenosine monophosphate and calcium levels, and tyrosine phosphorylation. In response to these signals, spermatozoa begin to express hyperactivated motility, facilitating their release from the oviductal epithelium and migration toward the site of fertilization. (5) These signals also elicit dynamic remodeling of the sperm surface architecture, priming these cells for interaction with the cumulus oocyte complex, the induction of acrosomal exocytosis, and ultimately fertilization of an ovum.

phenomenon is mediated by complex signaling pathways that facilitate cross-talk between the opposing cell types and effectively suppresses sperm activity. In this functionally repressed state, the spermatozoa of most mammals are able to maintained for between 2 and 5 days. Notable exceptions include some marsupials and bats, in which the duration of fertile sperm storage can be extended to between 15 days and several months, respectively (Holt, 2011). The dispersal of the sperm reservoir appears to be driven by the receipt of appropriate extracellular signal(s) coincident with ovulation, whereupon the spermatozoa are able to migrate rapidly toward the oocyte in a state of readiness for fertilization (Suarez, 2016). By the time the spermatozoa have reached the surface of the oocyte within the vicinity of the ampullary-isthmic junction (Fig. 1), they have experienced a functional transformation, including: (i) a transition to hyperactivated motility, (ii) remodeling of their surface architecture to facilitate the expression of receptors for the cumulus oocyte complex and (iii) the activation of the molecular machinery necessary for initiation of acrosomal exocytosis (Aitken and Nixon, 2013).

Mechanistic Basis of Capacitation

Capacitation-Associated Changes in Sperm Membrane Architecture

Much of our current understanding of the molecular basis of sperm capacitation is attributed to the ability to recapitulate this process with either ejaculated or cauda epididymal spermatozoa outside of the female reproductive tract. This *in vitro* approach necessitates the use of chemically defined medium comprising electrolytes (Na^+ , K^+ , Cl^- , HCO_3^- , Mg^{2+} , Ca^{2+} , PO_4^{3-}), energy substrates (glucose, pyruvate, and lactate), and a cholesterol sink; innovations that were first documented by Yanagimachi and Chang (1963). Once this practical milestone had been achieved, one of the first changes documented in capacitating mammalian spermatozoa was that of a substantial depletion of cholesterol from the plasma membrane (Davis et al., 1979). It has since been shown that sterols, such as cholesterol and desmosterol, are transferred from the sperm surface to acceptor molecules such as serum

albumin, high-density lipoproteins and apolipoproteins, thus promoting extensive membrane destabilization and the repositioning of membrane raft microdomains. Accordingly, cholesterol is able to exert a powerful decapacitation effect and, it is for this reason, that albumin features as an important constituent of *in vitro* capacitation media. Notably, the epididymis and male accessory organs also secrete additional proteinaceous decapacitation factors, such as phosphatidylethanolamine binding protein 1 (PEBP1), which bind spermatozoa and exert dual influence over their membrane stability and the modulation of intracellular signaling pathways (Aitken and Nixon, 2013). Acting in tandem with cholesterol, these decapacitation factors are thereby able to suppress the attainment of a capacitated state (Figs. 1 and 2). It follows that spermatozoa from PEBP1-deficient mice experience precocious capacitation and reduced reproductive success.

Notably, cholesterol depletion does not appear to occur uniformly across the entire sperm surface. Rather, there appears to be preferential cholesterol loss from lipid disordered, as opposed to lipid ordered, subdomains. The latter are discriminated on the basis of an enrichment of cholesterol, sphingomyelin, gangliosides, and phospholipids with saturated long-chain acyl groups; and are commonly referred to as either lipid or membrane raft microdomains. There is some evidence that selective sterol transfer from the sperm plasma membrane may be mediated by active cholesterol transporters, such as those of the ATP-binding cassette transporter superfamily. However, this process also appears to be augmented by capacitation-dependent oxidation of sterols. The increased hydrophilicity of the oxysterol products so formed promotes their transfer to albumin acceptors (Gadella and Boerke, 2016). This redox-regulated process is dependent on the presence of bicarbonate and reactive oxygen species (ROS) generation, such that antioxidant supplementation inhibits oxysterol formation and disrupts the capacitation of the spermatozoa. However, in addition to promoting oxysterol formation, both ROS and bicarbonate have been implicated in the modulation of a variety of alternative aspects of the capacitation cascade.

Notwithstanding the importance of sterol depletion in terms of promoting plasma membrane remodeling, once in the female genital tract spermatozoa do not experience pronounced structural changes until they undergo the acrosome reaction. Such observations fueled early speculation that capacitation must be primarily driven by chemical signals that sperm encounter within

Fig. 2 Model of the capacitation-associated intracellular signaling cascades. (1) The capacitation of mammalian spermatozoa is initiated upon removal of cholesterol and proteinaceous decapacitation factors from the plasma membrane. (2) The dissociation of such factors destabilizes the membrane, promotes sequestration of membrane raft microdomains and is permissive of Ca^{2+} and HCO_3^- influx through appropriate channels including CATSPER and $\text{Na}^+/\text{HCO}_3^-$ cotransporters, respectively. The resultant increase in intracellular calcium and HCO_3^- has been linked to alkalinization of the cell cytosol ($\uparrow \text{pH}_i$). (3) Acting in tandem, these factors stimulate the activity of soluble adenylyl cyclase (SACY), thereby elevating intracellular cAMP concentration. (4) Spermatozoa respond to high cAMP by activating PKA leading to the downstream serine/threonine phosphorylation of multiple substrates. (5) This results in the reciprocal activation of tyrosine kinase(s) and (6) inactivation of the serine/threonine phosphatase(s) (e.g., PP2A). (7) These combined events release spermatozoa from the suppressive mechanisms that normally keep PKA-dependent tyrosine phosphorylation under inhibitory control and thus promote a dramatic increase in the tyrosine phosphorylation of multiple sperm proteins; a pivotal form of posttranslational modification that underpins the functional transformation of spermatozoa and ultimately the attainment of a capacitated state. In addition to the canonical cAMP/PKA signaling pathway, there is a wealth of compelling experimental evidence supporting ancillary roles for (8) alternative signaling cascades such as the extracellular signal regulated kinase (ERKs) module of the mitogen-activated protein (MAP) kinase family and (9) various reactive oxygen species (e.g., in oxysterol formation/efflux, SACY activation, PP2A inactivation).

this environment. Support for this notion now rests with the recognition that spermatozoa are indeed exposed to a variety of extrinsic ligands that control the fate of the cell. Some of these interactions are designed to act early in the capacitation process to promote cell survival (e.g., prolactin) and to impede premature entry of the spermatozoa into capacitation (e.g., decapacitation factors) (Aitken and Nixon, 2013). The dissociation of such factors from the sperm surface makes way for alternative late-acting factors that prepare the cell for fertilization. Among these factors, bicarbonate and calcium ions appear to hold a central role in potentiating capacitation-associated cell signaling (Fig. 2).

Bicarbonate uptake into the maturing sperm cell is facilitated by $\text{Na}^+/\text{HCO}_3^-$ cotransport (Visconti et al., 2011). Thereafter it elicits a suite of interrelated responses, ranging from rapid compositional changes in phospholipid distribution and a concomitant increase in sperm membrane fluidity, activation of soluble adenylyl cyclase and induction of a cyclic adenosine monophosphate (cAMP)-dependent protein kinase A (PKA) signaling cascade, intracellular alkalinization, and hyperpolarization of the plasma membrane (Fig. 2). The aforementioned destabilizing effects of bicarbonate, acting synergistically with cholesterol efflux, have been attributed to stimulation of phospholipid scramblase and/or phospholipase enzymes (Gadella and Boerke, 2016). Such enzymatic activity leads to a dramatic reduction in the degree of phospholipid asymmetry, a property that renders the membrane more fusogenic, compatible with the downstream events of acrosomal exocytosis and oocyte plasma membrane (oolemma) fusion. These changes in membrane architecture are also conducive to the lateral redistribution, and concentration, of membrane rafts within the apical region of the sperm head. Such a position is compatible with a role in the mediation of oocyte recognition; a function that resonates with the sequestering of a multitude of receptors implicated in zona pellucida (ZP) adhesion into membrane rafts during capacitation. This also accords with the demonstration that detergent resistant membranes isolated from mouse and human spermatozoa are able to selectively adhere to the ZP of homologous oocytes (Nixon and Aitken, 2009).

An additional hallmark of capacitation is the hyperpolarization of the sperm plasma membrane. Analogous to most somatic cells, spermatozoa are able to maintain an intracellular ion concentration that differs from that of the extracellular environment and in so doing establish a membrane potential. As capacitation proceeds however, spermatozoa experience a hyperpolarization of their plasma membrane, a situation that arises from the closing of Na^+ channels, opening of a K^+ channel, or a combination of these events (Visconti et al., 2011). Such hyperpolarization has been postulated to de-repress Ca^{2+} voltage gated channels and thus facilitate the transient elevation of intracellular calcium needed to support the acrosome reaction. Accordingly, male mice lacking the sperm-specific K^+ channel, SLO3, produce spermatozoa that are refractory to capacitation-associated membrane hyperpolarization and the induction of acrosomal exocytosis, even in the presence of calcium ionophore (Visconti et al., 2011). As an additional tier of regulation, there is evidence that SLO3 activity is influenced by intracellular alkalinization and cAMP, thus reinforcing the importance of bicarbonate-mediated signaling events during capacitation.

Capacitation-Associated Intracellular Signaling

In addition to changes occurring at the plasma membrane, the elevated levels of bicarbonate that sperm encounter within the female reproductive tract also evoke a complex network of intracellular signaling responses (Fig. 2). The widely accepted model of capacitation-associated signaling depicts a sequential process whereby HCO_3^- and Ca^{2+} are positioned as primary drivers of a hierarchical signaling cascade involving increased production of the cAMP second messenger, activation of PKA, and tyrosine phosphorylation of a multitude of sperm proteins (Fig. 2). While this is a well-supported model, it is important to consider that these events are temporally separated into: (i) a subset of biochemical changes (i.e., cAMP generation and PKA activation) that reach maximum levels within as little as a minute following exposure to elevated HCO_3^- concentrations and (ii) a suite of downstream physiological changes (e.g., tyrosine phosphorylation, hyperactivated motility, and plasma membrane remodeling in preparation for acrosomal exocytosis and oocyte interaction) that proceed over a protracted timeframe of up to several hours (Gervasi and Visconti, 2016). Such differences in the activation kinetics of these interdependent correlates of capacitation suggest the necessity for cross-talk between multiple signaling pathways and the compartmentalization of the different processes needed for fertilization.

Canonical cAMP/PKA Signaling

The major regulatory roles assigned to bicarbonate during the early phases of capacitation occur via its direct activation of the atypical soluble adenylyl cyclase, ADCY10 (SACY) (Fig. 2). Accordingly, male mice lacking SACY express an infertility phenotype associated with pronounced sperm motility defects, which cannot be resolved through the application of exogenous cAMP analogues alone. Similarly, pharmacological inhibition strategies have confirmed SACY is required for sperm protein tyrosine phosphorylation and fertility but interestingly, not for hyperactivation or the acrosome reaction (Gervasi and Visconti, 2016). The regulation of these latter events may, instead, rest with classical membrane-bound adenylyl cyclases in a bicarbonate-independent manner. Nevertheless, SACY activation and a concomitant downregulation of phosphodiesterase activity, leads to an impressive increase in intracellular cAMP levels. This, in turn, elicits a rapid upregulation of PKA; a promiscuous serine-threonine protein kinase that acts as a key intermediary in the capacitation cascade (Fig. 2). Indeed, the ablation of the PKA catalytic subunit (PKA-C α 2) leads to a male sterility phenotype associated with defects in sperm capacitation, which mirror those observed in SACY knockout mice (i.e., the spermatozoa from both mouse models are refractory to protein tyrosine phosphorylation when held under capacitation-inducing conditions) (Gervasi and Visconti, 2016). This pivotal role of cAMP/PKA signaling also underpins the ability to accelerate the onset of capacitation in vitro via supplementation of incubation media with phosphodiesterase inhibitors and cAMP analogues.

Tyrosine Phosphorylation

PKA mediated phosphorylation affects the reciprocal activation of tyrosine kinase(s) (PTKs) and deactivation of protein phosphatases (Fig. 2). This results in precocious increases in protein tyrosine phosphorylation, a universal hallmark of capacitation documented in the spermatozoa of all studied eutherian mammals (Aitken and Nixon, 2013). Despite this, the primary kinases responsible for triggering tyrosine phosphorylation remain the matter of some debate. Recent experiments utilizing immunological approaches and small molecule inhibitors have highlighted putative roles for members of the SRC family tyrosine kinases (i.e., cSRC, ABL, FYN) as well as those of the focal adhesion kinase (FAK) family (i.e., FAK, PYK2) (Gervasi and Visconti, 2016). However, the use of transgenic models has challenged the involvement of such enzymes as direct effectors in the canonical capacitation signaling pathway. Rather, on the basis of such studies it is now held that SRC kinases act to phosphorylate, and thereby downregulate the activity of a serine/threonine phosphatase, likely PP2A (Gervasi and Visconti, 2016). This, in turn, releases spermatozoa from the suppressive mechanisms that normally keep PKA-dependent tyrosine phosphorylation under inhibitory control. In terms of alternative tyrosine kinases, several lines of evidence now support a primary role of FER (fer (fps/fes related) tyrosine kinase). Indeed, spermatozoa from mice bearing a kinase-inactivating mutation in *Fer* are refractory to capacitation-associated increases in tyrosine phosphorylation and present with defects in *in vitro* fertilization. Unexpectedly however, these mice retain their fertility, thus challenging the current paradigm that capacitation-associated tyrosine phosphorylation is indispensable for mammalian fertilization (Gervasi and Visconti, 2016).

The functional significance of tyrosine phosphorylation may be resolved by determining the identity of the cohort of sperm proteins that are subjected to this form of modification during capacitation. Although this goal has yet to be fully realized, it is evident that the majority of phosphotyrosine substrates reside within the principal piece of the sperm flagellum. In human spermatozoa for instance, the most prominent targets for capacitation-associated tyrosine phosphorylation are A-kinase anchoring protein (AKAP) 4 (formerly AKAP82) and its precursor pro-AKAP4, both of which represent key structural elements of the fibrous sheath (Bailey, 2010). Owing to the ability of AKAPs to sequester PKA, these findings lend support to the existence of intimate cross-talk between PKA and protein tyrosine kinase pathways. They also raise the prospect that tyrosine phosphorylation may regulate hyperactivation. This notion is congruous with the functions assigned to the fibrous sheath in terms of regulating the degree of flexibility and shape of the flagellar beat during sperm motility, as well as serving as a scaffold for several signaling and/or metabolic pathways. Similarly, Ca^{2+} -binding tyrosine-phosphorylation-regulated protein (CABYR), an ancillary protein associated with the development of the fibrous sheath and regulation of progressive motility, also undergoes tyrosine phosphorylation during capacitation (Bailey, 2010).

Capacitation is also associated with additional foci of tyrosine phosphorylation within the sperm head, and these substrates may be equally, if not more, significant to the attainment of functional competence than those of the flagellum. For instance, the capacitation of boar spermatozoa is correlated with a marked increase in the tyrosine phosphorylation of head-surface proteins; with the major substrate being ACRBP, a (pro)acrosin binding protein that possesses affinity for the zona pellucida (ZP) (Bailey, 2010). A similar situation has also been documented in mouse spermatozoa whereby capacitation is correlated with the appearance of phosphotyrosine residues on the exterior leaflet of the membrane overlying the anterior region of the sperm head. The subset of spermatozoa bearing this hallmark of capacitation correspond to those with the ability to adhere to the ZP, suggesting that tyrosine phosphorylation plays an intermediary role in remodeling the sperm surface to enable ZP recognition. Accordingly, the dominant phosphotyrosine substrates in this domain have been identified as molecular chaperones (namely, HSP90B1 and HSPD1), proteins that are hypothesized to orchestrate the assembly and/or presentation of ZP recognition complex(es) on the sperm surface (Dun et al., 2012).

Work conducted in human spermatozoa suggest that these cells may be primed for oocyte interactions via similar capacitation-associated mechanisms, although in our species this pivotal role appears to rest with HSPA2, an alternative, testis-enriched molecular chaperone. Like HSPD1 and HSP90B1 in the mouse, human sperm HSPA2 is also subject to capacitation-associated tyrosine phosphorylation and is capable of interacting with a number of client proteins (e.g., ARSA, SPAM1, ACE1, PDIA6) that possess affinity for the cumulus-oocyte complex (Nixon et al., 2017). Another notable target for tyrosine phosphorylation within the head of capacitating human spermatozoa is valosin-containing protein (VCP). VCP is a homologue of the SNARE-interacting protein, NSF, which regulates membrane fusion and exocytosis. Thus, the tyrosine phosphorylation of VCP, coupled with its translocation from the connecting piece to the anterior head, could contribute to modulation of acrosomal responsiveness. Alternatively, as is the case for HSPA2, VCP may act to chaperone membrane fusion machinery to their site of action during plasma-acrosomal membrane fusion (Bailey, 2010).

While by no means exhaustive, this brief survey of experimentally validated substrates for capacitation-associated tyrosine phosphorylation does support the importance of this form of posttranslational modification in the priming of spermatozoa for fertilization. Moreover, it suggests that the pervasive impact of tyrosine phosphorylation extends across functional parameters as diverse as motility, surface remodeling, acrosomal exocytosis, and ultimately oolemmal fusion. It is therefore perhaps not surprising that capacitation may encompass alternative tyrosine phosphorylation pathways. Indeed, there is evidence that the extracellular signal regulated kinase (ERK) module of the mitogen-activated protein (MAP) kinase family, may exert regulatory control over certain aspects of capacitation. The fact that key elements of the ERK signaling pathway localize within the peri-acrosomal region of the sperm head suggests that this pathway influences the surface modifications that occur within this domain as capacitation proceeds. This agrees with the demonstration that inhibition of ERK signaling reduces the ability of mouse spermatozoa to engage

in ZP interactions. While there is also some evidence for cross-talk between the cAMP/PKA and ERK pathways during capacitation, the precise nature of this interaction is not well understood (Bailey, 2010).

Intracellular Ca^{2+} and pH

Acting in conjunction with bicarbonate, capacitating spermatozoa experience dramatic changes in intracellular levels of both Ca^{2+} and H^+ ions (Fig. 2). The accompanying increase in $[\text{Ca}^{2+}]_i$ and alkalization of the cell cytosol have been attributed primary messenger status in terms of directly supporting sperm motility and the acrosome reaction (Visconti et al., 2011). They are however, also of fundamental importance in promoting capacitation associated signaling. Indeed, loss- and gain-of-function approaches have established that capacitation is Ca^{2+} -dependent, as are the initiation and maintenance of hyperactivated motility and the acrosome reaction. While informative, this scenario does present some problems owing to the difficulty in differentiating the indirect effects of $[\text{Ca}^{2+}]_i/\text{pH}_i$ during capacitation from that of their direct role in motility and the acrosome reaction. In accounting for the regulation of these two opposing phenomena, it has been postulated that differing mechanisms of calcium entry into the sperm may be particularly relevant (Bailey, 2010). In this context, spermatozoa are known to harbor numerous transporters that could serve as principle candidates responsible for manipulation of Ca^{2+} influx (e.g., CAV and CATSPER channels, $\text{Na}^+/\text{Ca}^{2+}$ exchangers, Ca^{2+} ATPases). Alternatively, they also possess several proteins implicated in Ca^{2+} release from intracellular stores (e.g., IP3 receptors, ryanodine receptors, two-pore channel proteins, and SERCA/SPM ATPases). Notably, the activity of sperm calcium channels such as the voltage dependent calcium channel (VDCC) and the CATSPER family are strongly potentiated by intracellular alkalization, thus accounting for the intimate relationship between $[\text{Ca}^{2+}]_i$ and pH_i in modulating capacitation-associated signaling (Visconti et al., 2011).

Redox Regulation of Capacitation

While the involvement of ROS in sperm capacitation is well established, the identity of the free radical species and the regulatory forces they impose on capacitation has remained the subject of some controversy (Aitken et al., 2015). This situation reflects the existence of compelling evidence implicating key roles for hydrogen peroxide, superoxide anion, and the peroxynitrite anion. In reality, the rapid interconversion of these various reactive species means it is likely that several different redox entities could be involved in various aspects of the capacitation process (Aitken et al., 2015). By way of illustration, the global elevation of protein tyrosine phosphorylation levels that accompany capacitation are intimately tied to the suppression of tyrosine phosphatase activity. This family of enzymes possess a crucial cysteine residue located within their active site that must be held in a reduced state for the expression of phosphatase activity. Potent oxidants generated during sperm capacitation such as hydrogen peroxide and peroxynitrite are both capable of oxidizing this cysteine residue and thus inactivating tyrosine phosphatase activity. Alternatively, superoxide can directly modulate the activity of soluble adenylyl cyclase, thus contributing to increased intracellular levels of cAMP, which drives downstream tyrosine kinase activity. Hydrogen peroxide may also indirectly influence adenylyl cyclase activity thereby creating a self-perpetuating cascade involving ROS generation, adenylyl cyclase activation and tyrosine phosphorylation (Fig. 2).

Additional evidence affirming the role of ROS in the molecular mechanisms regulating sperm capacitation comes from analysis of the biological effects elicited by ROS-specific scavengers. For instance, the elevation of tyrosine phosphorylation during human sperm capacitation can be suppressed via the addition of exogenous catalase to scavenge the hydrogen peroxide generated by these cells. Similarly, membrane permeant ROS scavengers such as 2-mercaptoethanol have been reported to have a profound inhibitory impact on tyrosine phosphorylation. The converse is also true, whereby the direct addition of hydrogen peroxide to mammalian spermatozoa can elicit the tyrosine phosphorylation events associated with capacitation as well as trigger the acrosome reaction (Aitken et al., 2015).

These collective data highlight the phosphatases and kinases regulating tyrosine phosphorylation as being major targets for redox regulation of capacitation. Despite this knowledge, the source of the free radicals that contribute to capacitation remains to be fully resolved, with the involvement of various enzymatic and nonenzymatic biochemical pathways currently under consideration. Irrespective of the source, the ROS that drives capacitation presents spermatozoa with a unique challenge. Indeed, owing to their highly specialized architecture, spermatozoa are inherently vulnerable to oxidative stress. This has prompted the hypothesis that sperm capacitation and the entry of these cells into the intrinsic apoptotic cascade are a continuum, with the ROS that drive tyrosine phosphorylation, cAMP production and cholesterol efflux from the plasma membrane ultimately inducing a state of apoptosis (Aitken et al., 2015). It is for this reason that capacitated spermatozoa rapidly succumb to cell senescence if, upon reaching the site of fertilization, they fail to encounter an oocyte.

Summary

The spermatozoa of all mammalian species acquire the ability to fertilize an ovum during their capacitation within the female reproductive tract. This functional transformation proceeds through a sophisticated hierarchy of biochemical and biophysical changes, the control of which rests with both intrinsic and extrinsic factors. The culmination of capacitation is the generation of

a population of highly specialized spermatozoa that are primed to undergo the acrosome reaction and possess the correct surface architecture to interact with the cumulus oocyte complex and thereby initiate fertilization.

Introduction

Mammalian fertilization is a complex process involving a series of coordinated steps. Differently from the situation in most invertebrates and lower vertebrates in which testicular spermatozoa have full fertilizing ability, the highly differentiated mammalian sperm leaving the testis are immotile and do not have the ability to fertilize an egg. To become competent, mammalian sperm need first to undergo a maturation process while passing through the epididymis that confers them progressive motility and the ability to interact with the egg. Mature sperm leaving the epididymis, however, still do not have the immediate capacity to fertilize an egg requiring to undergo another process known as capacitation that occurs while they are ascending through the female tract (Yanagimachi, 1994). After maturation and capacitation, sperm become able to reach, recognize and fertilize the eutherian egg which is ovulated surrounded by two vestments: the cumulus oophorus, a mass of granulosa cells embedded in a matrix of hyaluronic acid, and a glycoprotein coat known as zona pellucida (ZP) (Fig. 1A).

Whereas in all mammals (i.e., monotremes, marsupials, and eutherians), fertilization requires the previous occurrence of the acrosome reaction (AR), an exocytotic event in the head, in eutheria, fertilization also requires the development of a special vigorous and intermittent sperm motility known as hyperactivation. In addition, whereas in mammals the AR involves the release of the acrosomal enzymes as a result of the fusion between the plasma membrane and the underlying acrosomal membrane, in eutheria, it has another important consequence such as the acquisition of fusogenicity of the plasma membrane covering the equatorial segment (Fig. 1B).

Fertilization in eutherian mammals occurs in the ampulla of the oviduct and involves the following successive steps (a) penetration of the cumulus oophorus, (b) binding of sperm to the ZP, (c) penetration of the ZP and, finally, (d) fusion of sperm with the egg plasma membrane (Fig. 2). Each of these steps has different requirements regarding the AR and hyperactivation which are summarized in Fig. 3.

This article will describe the different strategies and molecular mechanisms involved in each of the stages of the fertilization process focusing on eutherian mammals and mainly in rodent models.

Penetration of the Cumulus Oophorus

One of the unique characteristics of most eutherian mammals is the presence of the cumulus oophorus surrounding the oocytes at the time of the ovulation (Bedford, 2014). Thus, penetration of sperm through this cumulus mass becomes the first step towards a successful fertilization. Although not essential, it is widely accepted that the presence of the cumulus oophorus is beneficial for fertilization and reduces individual variations in male fertility. The cumulus layers increase the apparent size of the oocyte and, therefore, the chances that a spermatozoon reaches the oocyte within the ampulla (Bedford, 2014). Evidence also indicates that the radial distribution of the cumulus cells allows the formation of a gradient of chemoattractant molecules secreted by these cells (i.e., progesterone, CRISP1, natriuretic peptides) that guides hyperactivated sperm towards the oocyte (Armon and Eisenbach, 2011). The cumulus may also facilitate fertilization by prolonging the fertile life of the eggs, by preventing spermatozoa to swim away, by filtering those spermatozoa that are unable to interact with the egg, and by enhancing sperm capacitation and AR (Yanagimachi, 1994). In this sense, whereas it is clear that only capacitated sperm can penetrate the cumulus mass, controversial evidence exists regarding the acrosomal status of sperm penetrating the cumulus layers. As described in more detail below, an early model

Fig. 2 Successive stages of gamete interaction during mammalian fertilization. (A) Sperm contact and penetrate the cumulus oophorus; (B) sperm binds to the zona pellucida; (C) sperm penetrates de zona pellucida reaching the perivitelline space; (D) sperm fuses with the plasma membrane of the egg.

Fig. 3 Requirements of AR and hyperactivation for each stage of gamete interaction. *Solid and dashed lines* refer to an absolute or potential requirement, respectively.

proposed that acrosome intact sperm pass through the cumulus layer and undergo the AR at the ZP level (Florman and Fissore, 2015). However, more recent studies show that the majority of sperm have already completed their AR before entering the cumulus oophorus, reaching the ZP without acrosome (Jin et al., 2011; Hino et al., 2016; Florman and Fissore, 2015). Recent observations by video-recording of sperm within the oviduct show that reacted sperm do not spend much time in the cumulus layers but quickly reach the ZP and swim away from a fertilized egg to enter the cumulus of a nearby unfertilized egg (Hino et al., 2016), supporting a role for the ZP but not for the cumulus oophorus in the prevention of polyspermy.

The molecular mechanisms leading to the sperm entry into the cumulus and subsequent penetration are still poorly understood. It has been proposed that mouse sperm hyaluronidases SPAM1 (formerly known as PH-20) and HYAL5 were both involved in

penetration through the cumulus matrix in acrosome-intact and acrosome-reacted sperm. However, studies using sperm lacking each of these proteins showed that, in spite of a reduced ability to disperse the cumulus mass in SPAM1 knockout mice, the males were fertile (Kimura et al., 2009). The generation of HYAL5/SPAM1 double-knockout mice will provide important information on the relevance of sperm hyaluronidases for the cumulus penetration.

It has also been postulated that sperm hyperactivation may be necessary for cumulus penetration. Evidence favoring this possibility comes from early studies showing that hyperactivated hamster or mouse sperm penetrate more efficiently than fresh sperm, a viscoelastic medium which resembles that from the viscoelastic cumulus matrix (Suarez and Dai, 1992). In addition, it has been reported that sperm lacking testicular CRISP2 have impaired ability to hyperactivate and to penetrate cumulus–oocyte complex in vitro (Brukman et al., 2016). However, further studies are required to clarify the need of hyperactivation for cumulus penetration.

Sperm Binding to the ZP

As mentioned above, besides the cumulus oophorus, the eutherian mammalian egg is ovulated surrounded by the ZP, a thick and elastic coat that plays important roles before and after fertilization. The ZP protects eggs and embryos from physical damage and from sticking to the oviductal walls, contributes to create the specialized microenvironment of the perivitelline space, participates in the mechanisms of prevention of polyspermy and is essential for the development of the preimplantation embryo.

After having penetrated the cumulus oophorus, sperm first bind to and then penetrate the ZP. Sperm–ZP binding has been extensively studied, especially since the biochemical characterization of the protein composition of the ZP in the 80's. Several reports, mainly from Wassarman's laboratory, revealed that the ZP is basically composed by three or four proteins depending on the species that is, ZP1, ZP2, ZP3, and ZP4, significantly contributing to the elucidation of the molecular mechanisms involved in sperm–ZP interaction. As clearly summarized by Florman and Fissore (2015), it was generally believed that the occurrence of the AR which is essential for subsequent steps (i.e., ZP-penetration and gamete fusion) is triggered upon the binding of sperm to the ZP. Moreover, ZP3 was postulated as the molecule involved in both binding of intact sperm to the ZP (primary binding) and induction of the AR, while ZP2 was proposed to participate in the binding of sperm to the ZP after the AR (secondary binding). The use of genetic modified animals for ZP genes, however, opened new insights on the molecular mechanisms involved in gamete recognition showing the critical roles played by the whole ZP structure and the state of ZP2 (cleaved or uncleaved) in sperm–ZP binding (Avella et al., 2013). In addition, as stated above, recent observations using life imaging revealed that most fertilizing sperm undergo the AR before reaching the ZP (Jin et al., 2011), supporting that sperm–ZP interaction is not critical for triggering the AR as previously proposed.

Contrary to the few ZP molecules involved in sperm–ZP binding, numerous sperm proteins have been proposed to be involved in this stage of the fertilization process (i.e. proacrosin, zonadhesin, P56, galactosyltransferase, SED1, etc.) (Okabe, 2014). The use of knockout mice for these molecules, however, questioned their roles in fertilization revealing that most of them were dispensable for fertility. Knockout mice for other molecules proposed to be involved in sperm–ZP binding such as calmegin, Ace (angiotensin-converting enzyme) and members of the ADAM family (ADAM1a, ADAM2, and ADAM3) exhibit sperm with impaired ability to bind to the ZP and either lack or have an aberrant distribution of ADAM3, a sperm surface protein that seems to emerge as a key molecule for gamete interaction (Okabe, 2014). Interestingly, these knockout mice are infertile due to an unexpected sperm inability to migrate into the oviduct, suggesting that oviduct migration and sperm–ZP binding might share a common mechanism. Therefore, evidence seems to support the idea that sperm–ZP interaction is not a simple ligand-receptor event as originally proposed but rather a complex process involving different molecules and recognition mechanisms. Finally, the finding that sperm that are unable to bind to the ZP under in vitro conditions are capable of fertilizing eggs when inseminated in the oviduct led some investigators to reconsider the need of a sperm–ZP binding step for fertilization (Okabe, 2014).

Penetration of the ZP

Sperm penetration through the ZP is the most species-specific stage of the fertilization process. It is a relatively rapid event in which sperm penetrates the ZP at a 45 degree angle. In all mammals, the occurrence of the AR is an absolute requirement for this stage. However, whereas in sub-theria (monotremes and marsupials) ZP-penetration involves a rapid degradation of the coat by the enzymes released from acrosome-reacted spermatozoa, in eutherian mammals, this stage seems to be mediated by mechanical rather than enzymatic mechanisms. Several observations support this idea. The fertilizing sperm passing through the ZP moves the tail vigorously while its narrow head seems to physically cut the zona, it leaves a very thin and curved slit in the zona which completely differs from the enzymatic halo observed in the ZP of other mammals, and inhibitors of acrosomal enzymes proposed to be involved in ZP penetration (i.e., acrosin) impair the previous stage of sperm–ZP binding (Yanagimachi, 1994; Bedford, 2014).

Strong evidence indicates that sperm need to be hyperactivated in order to gain the strength to penetrate the ZP. Hyperactivation development is mediated by the activation of CatSper, the principal sperm calcium channel present in mammals (Ren et al., 2001). Male mice lacking CatSper are infertile because their sperm do not hyperactivate and cannot penetrate the ZP (Carlson et al., 2003), supporting the key role of hyperactivation for successful penetration of the ZP. Thus, although not completely excluded from participating in ZP penetration, acrosomal enzymes in eutheria may be more relevant for other events of the fertilization process such as sperm binding to the ZP or development of the fusogenic properties of the equatorial segment during the AR.

The need of physical thrust for ZP penetration may be associated to the thick and robust ZP of eutherian eggs (Bedford, 2014). Interestingly, accompanying this special nature of the ZP, eutherian sperm also exhibit special features such as a rigid and flat head which allows it to oscillate in the plane during ZP penetration and a stable inner acrosomal membrane (Fig. 1B) which is the one that directly bears the physical effort inherent to ZP penetration. As a consequence of its stability, the inner acrosomal membrane do not exhibit the fusogenic properties required for subsequent gamete fusion which, in eutheria, are preserved on the plasma membrane over the equatorial segment.

Sperm–Egg Fusion

After penetration of the egg vestments, the acrosome-reacted sperm quickly traverses the perivitelline space, a special microenvironment that favors gamete fusion. Evidence shows that gamete fusion in mammals involves a first step in which the sperm binds to the egg plasma membrane followed by a second step of gamete membrane fusion. In this regard, differently from sub-therian mammals in which sperm fuses with the egg through the inner acrosomal membrane, the eutherian sperm fuses with the egg through the equatorial segment of the sperm head (Bedford, 2014). In fact, the AR is an absolute requirement for gamete fusion because only after the occurrence of this event the equatorial segment becomes able to fuse with the egg plasma membrane (Yanagimachi, 1994; Bedford, 2014). The acrosome-reacted sperm fuse with the microvilli present on the entire egg surface except on the area overlying the meiotic spindle, a region through which gamete fusion rarely occurs. In contrast to the absolute need for the AR, evidence indicates that hyperactivation is not required for gamete fusion but that a specific flagellum beat mode is needed for inducing this process (Ravaux et al., 2016). After an abrupt reduction of the sperm tail movement, indicative that gamete fusion has occurred, all the sperm is gradually incorporated into the egg cytoplasm. While the posterior head and tail are incorporated through a membrane fusion process, the anterior region of the head is internalized by a process similar to phagocytosis (Yanagimachi, 1994).

Although gamete fusion is a key step of fertilization, little is known about the molecular mechanisms involved in this process. Proteins involved in gamete fusion were initially identified using specific antibodies to inhibit *in vitro* fertilization. Subsequent gene-disruption experiments revealed that many of these proteins participate in events that precede gamete fusion or that seem to be inessential (Okabe, 2014). Knockout mice for members of the ADAM protein family (i.e., fertilin) postulated as mediators of the fusion process were infertile due to an unexpected phenotype not related to gamete fusion: failure of sperm to migrate to the oviduct *in vivo* and to bind to the ZP *in vitro* (Okabe, 2014). *In vitro* fertilization studies carried out in the presence of antibodies or proteins revealed the involvement of CRISP1 and CRISP2 in gamete fusion through their interaction with complementary sites localized in the egg surface. Although mice lacking these proteins are fertile, their sperm exhibit an impaired fusion ability supporting their relevance for gamete fusion (Da Ros et al., 2008; Brukman et al., 2016). The only sperm protein that proved to be essential for gamete fusion so far is IZUMO, a testis specific member of the immunoglobulin (Ig) superfamily of proteins. Interestingly, IZUMO knockout males are infertile because of an impaired sperm ability to fuse with the egg plasma membrane (Inoue et al., 2005). The tetraspanin CD9 has been identified as an egg plasma membrane protein essential for gamete fusion in mammals (Miyado et al., 2000) and, more recently, the molecule folate receptor 4 (FOLR4), named JUNO, was found to be the egg receptor for sperm IZUMO (Bianchi et al., 2014). IZUMO–JUNO interaction is very weak, and is proposed to mediate the initial adhesion step between gametes but not their fusion. The correct interaction between JUNO–IZUMO molecules would be strengthened by CD9 which has been also proposed as organizer of the microdomains involved in membrane fusion. Whereas these observations provide information on the ligand–receptor interactions required for gamete fusion, the identity of the molecules directly involved in sperm–egg membrane fusion process itself (fusogens) still remain unknown.

Following gamete fusion, the egg initiates a series of morphological and biochemical events known as “activation” that involves resumption of meiosis and block of polyspermy, and leads to cell division/differentiation and the formation of a new individual.

Glossary

Acrosome A secretory vesicle covering the anterior portion of the sperm head underneath the plasma membrane, which consists of a matrix enfolded within a continuous two-layer membrane system; the inner acrosomal membrane and the outer acrosomal membrane.

Acrosome reaction An exocytotic event that is an essential prerequisite to successful fertilization, and occurs in capacitated sperm following a trigger located in the surroundings of the egg. Exocytosis involves the fusion and vesiculation of the plasma membrane overlying the acrosome and the outer acrosomal membrane, so that acrosome contents are released.

Spontaneous acrosome reaction (sAR) Release of acrosome contents under some conditions, in the absence of a trigger, lead to an impairment of this well-regulated exocytotic event and a lowered incidence of a successful fertilization.

Zona pellucida An oocyte-specific extracellular matrix that surrounds the egg and is responsible for specific-specific binding of sperm and induction of the acrosome reaction of bound sperm; the components of the zona pellucida are glycoproteins.

Introduction

The acrosome is a secretory vesicle covering the anterior portion of the sperm head underneath the plasma membrane (PM). This structure is a derivative of the Golgi apparatus, and consists of a matrix enfolded within a continuous two-layer membrane system; the outer acrosomal membrane (OAM) adjoining the sperm PM and the inner acrosomal membrane located near the nuclear envelope. Although the size and shape of the acrosome are different among various species, its basic structure is the same in all eutherian mammals. Sperm must have properly formed acrosomes to be functional in the fertilization process; men or mice carrying mutations affecting the formation or function of the sperm acrosome are infertile or display severe subfertility. In mammals, the acrosome reaction (AR) involves the fusion of the OAM with the overlying PM, thus creating mixed membrane vesicles which later on spread over. AR was studied using intact cells, permeabilized cells and a cell-free system (CFS), in which the membrane fusion event is isolated from other stages of the signaling cascades. In this CFS of sperm AR, PM, and OAM are extracted and the fusion between them was monitored. It was found that both membrane species are primed to fuse during capacitation. The requirement for alkaline pH (7.4) and high Ca^{2+} concentration (about 20 μM) for successful fusion in the CFS mimics those of AR in intact cells. It was discovered that during capacitation, the acrosome undergoes swelling resulting in changes in distance between the OAM and the PM, and that the probable contact between these two membranes could establish the docking or formation of fusion pores.

The head of the acrosome-reacted sperm is turned into an arrowhead-shaped structure allowing the mechanical penetration into the egg. The AR is a well-regulated exocytotic event, which is an absolute prerequisite for successful fertilization. Physiological AR can occur only in sperm that undergo some biochemical transformations in the female reproductive tract, collectively called capacitation.

Functional Significance and Site of the Acrosome Reaction

In many animals the eggs are surrounded by glycoprotein coats, through which the sperm cell must pass in order to reach the egg PM (oolemma). In nonmammalian species the acrosomal content, released after the AR, dissolve the coat to produce a hole through which the spermatozoon can burrow into the egg. In mammals the egg contains a glycoprotein envelope called the zona pellucida (ZP). In the metaphase II-arrested egg, the ZP is further surrounded by the cumulus oophorus, which consists of cumulus cells and their matrix. In many species, sperm that undergo premature AR generally display reduced rate of fertility, due to a failure to penetrate the cumulus oophorus and interact with the egg ZP. It is generally accepted, that only acrosome-intact sperm can bind to the ZP resulting in the occurrence of the AR. Although the ZP of mouse egg and many other species has the ability to induce the AR, it has been demonstrated that at least in the mouse, most fertilizing spermatozoa were acrosome-reacted before reaching the ZP. It was reported that fertilizing mouse sperm begin their AR in the upper isthmus of the oviduct. During the period of fertilization within the oviduct, acrosome-reacted sperm were seen throughout the isthmus, but with higher incidence in the upper than in the mid- and lower segment of the isthmus. Moreover, these authors showed that very few spermatozoa were present in the ampulla, and almost all were acrosome reacted. All fertilizing mouse sperm within the oviduct begin to react before ascending from the isthmus to the ampulla. Others have claimed that cumulus cell mass may be the site of acrosomal exocytosis, a concept supported by recent studies showing that syndecan-1 is present on cumulus cells and possesses the ability to induce exocytosis in vivo. Thus, the site of the AR in vivo should be reconsidered, and the concept regarding the ZP as the only site of physiological AR should be reevaluated. The acrosome-reacted spermatozoon that penetrated the egg-ZP, has the ability to interact and fuse with the egg-PM leading to the zona reaction, a process which prevents polyspermy. A critical protein for sperm-egg fusion is IZUMO1, which is

localized on the acrosomal membrane. As a consequence of acrosomal exocytosis, this protein relocates to the surface of the equatorial region, and sperm become fusion-competent. Thus, the AR has at least dual functions: it renders spermatozoa capable of penetrating through the ZP, and fusing with the egg PM.

Acrosome Reaction Triggers

The AR depends upon an increase of intracellular Ca^{2+} concentration ($[\text{Ca}^{2+}]_i$) and PH. This can be artificially established using Ca^{2+} -ionophore A23187, which is a $\text{Ca}^{2+}/2\text{H}^+$ exchanger that triggers the AR when added to capacitated sperm. The mechanism within the spermatozoon, that regulates $[\text{Ca}^{2+}]_i$ for the AR, involves the PM and the acrosome which is a Ca^{2+} storage. Extracellular concentration of Ca^{2+} is in the mM range, and intracellular concentration is in the nM range. The sperm PM contains various Ca^{2+} -channels that mediate Ca^{2+} influx, as well as Ca^{2+} -pump (Ca^{2+} -ATPase) and $3\text{Na}^+/\text{Ca}^{2+}$ exchanger, two systems for Ca^{2+} exclusion from the cell.

The physiologically relevant trigger of the AR that has received the greatest experimental attention is the ZP. Isolated ZP can bind only to acrosome-intact sperm, and can cause the AR. Sperm that contain bound ZP, cannot fertilize the egg, suggesting that the ZP is the physiological ligand that triggers the AR. These initial experiments were carried out in the mouse, and were later on performed in other species including human. Binding of sperm to ZP activates a poorly selective cation channel leading to membrane depolarization and Gi-protein-dependent increase in intracellular PH followed by opening of a voltage sensitive Ca^{2+} channel leading to an increase in $[\text{Ca}^{2+}]_i$.

Spermatozoa also contain several receptors, like P_2 -purinoceptor (activated by extracellular ATP), epidermal-growth-factor-receptor (EGFR), G-protein-coupled-receptors (GPCRs) like lysophosphatidic acid receptor (LPA-R), angiotensin II receptor (AngII-R), and Zn^{2+} -R, progesterone-activated CatSper (a sperm specific Ca^{2+} -channel) and more, all of which can cause an increase in intracellular Ca^{2+} concentrations and trigger the AR. The ligands of these receptors are found in the female reproductive tract at concentrations that can trigger the AR. As mentioned above, for many years the predominant concept was that true AR occurs only and immediately after binding to the ZP, and so this list of triggers were considered to cause false AR. The finding that mouse sperm which undergone AR before reaching the egg are fertile, suggests that other physiological triggers besides ZP might cause true AR if it occurs in the surroundings of the egg. If AR occurs far from the egg, before reaching the isthmus, such sperm is unable to reach the egg in the oviduct and would not be able to fertilize it. We can think of this as false AR, which might be a part of a selection process. It is known that out of 20 million sperm that were transferred to the female, only 10–100 capacitated sperm arrive to the fertilization site. Thus, the AR may also be considered as a selection process designed to ensure the delivery of the genetically selected sperm to the fertilization site.

Signaling Mechanisms in the Acrosome Reaction

During sperm capacitation actin monomers are polymerized into F-actin polymers, and prior to the AR the actin polymers should be dispersed to allow the contact between the OAM and the overlying PM. The increase in intracellular Ca^{2+} levels prior to the AR activates phospholipase C (PLC) to hydrolyse PIP_2 leading to the release of PIP_2 -bound tyrosine-phosphorylated-gelsolin, which undergoes dephosphorylation/activation by Ca^{2+} . Gelsolin is an actin-severing-protein, which causes fast F-actin depolymerisation prior to the AR. All AR triggers, including ZP, cause an increase in Ca^{2+} influx resulting in an increase in intracellular Ca^{2+} concentrations ($[\text{Ca}^{2+}]_i$). ZP triggers a transient elevation of $[\text{Ca}^{2+}]_i$, which is carried out by a low voltage-activated Ca^{2+} channel, a member of the Ca_v3 family. The sustained Ca^{2+} response occurring after ZP binding to sperm is conducted by TRPC Ca^{2+} -channel. ZP activation of TRPC channels leads also to activation of PI3K to produce PIP_3 , which acts as docking sites for Akt (PKB) and $\text{PKC}\zeta$, two kinases that mediate downstream stages of the AR.

The increase in $[\text{Ca}^{2+}]_i$ described above is necessary, but not enough, to induce the AR. EPAC-dependent Ca^{2+} release from the acrosome should occur in order to achieve the AR. The cyclic adenosine monophosphate (cAMP)-dependent EPAC is an exchange factor, which activates the small GTPases Rap1 and Rab3A by replacing GDP by GTP. EPAC activates $\text{PLC}\epsilon$, which is required for the AR downstream to Rap1 and upstream to intraacrosomal Ca^{2+} mobilization. In turn, $\text{PLC}\epsilon$ hydrolyses PIP_2 to IP_3 , and diacylglycerol (DAG). IP_3 activates IP_3 -receptor, localized in the OAM, to release Ca^{2+} from the acrosome and DAG activates PKC leading to the AR. EPAC can also activate the SNARE protein, known to participate in the membranes fusion in the AR process. When the PM and the OAM are tethered, SNARE forms a trans complex that brings the two bilayers in close proximity.

The list of proteins that participate in the AR also include Rab3A, α -SNAP, NSF, synaptotagmin, calmodulin, dynamin, and complexin.

The AR also depends on signaling molecules like MUPP1, a membrane raft-associated molecular organizer. MUPP1 controls the initial tethering and docking of the acrosomal vesicle, whereas the SNARE protein syntaxin-2 mediates the final step of acrosomal fusion. Inhibition of the Ca^{2+} -ATPase (Ca^{2+} -pump), localized in the OAM and transports Ca^{2+} into the acrosome, causes reduction in intraacrosomal Ca^{2+} concentration resulting in significant increase in cytosolic $[\text{Ca}^{2+}]_i$ due to the opening of the PM store-operated- Ca^{2+} -channel leading to AR.

Progesterone, secreted from the cumulus cells, activates the sperm specific Ca^{2+} -channel CatSper in the sperm tail, and stimulates indirectly the AR. Mouse sperm treated with ZP exhibited a CatSper-dependent Ca^{2+} influx that progressed from the tail to the head leading to the AR.

Sperm EGFR is partially activated during incubation under capacitated conditions. Further activation of the EGFR by EGF or by isolated ZP at the end of the capacitation enhances intracellular Ca^{2+} concentration leading to F-actin breakdown and allows the AR to take place. Under in vivo conditions, the EGFR can be directly activated by its known ligand EGF, which is present in the female reproductive tract, and indirectly by the cascade PKA-Src-EGFR. Moreover, the AR can be induced by GPCRs via the transactivation

of the EGFR by a signaling pathway involving PKA, SRC family tyrosine kinase and metalloproteinase, and the EGFR downstream effectors PI3K, PLC, and PKC. Regarding the role of the heterotrimeric G-proteins in the AR, it was shown that ZP-dependent intracellular alkalization does not occur when G-protein stimulation is inhibited. Under physiological conditions, sperm PKA is indirectly activated mainly by bicarbonate, which activates the soluble adenylyl cyclase (sAC) to produce cAMP the activator of PKA. GPCR activators like angiotensin II or lysophosphatidic acid are physiological components present in the female reproductive tract.

We suggested that the $\alpha 7$ -nicotinic-acetylcholine receptor ($\alpha 7$ nAChR) might be a sperm receptor activated by ZP to induce EGFR-mediated AR. We found that isolated ZP or $\alpha 7$ agonists induced the AR in sperm from WT but not $\alpha 7$ -null spermatozoa, and the induced AR was inhibited by $\alpha 7$ or EGFR antagonists. Moreover, $\alpha 7$ -null sperm showed very little binding to the egg, and microfluidic affinity in vitro assay clearly showed that $\alpha 7$ nAChR, as well as EGFR, interacted with ZP3. Induction of EGFR activation and the AR by $\alpha 7$ agonist was inhibited by a Src family kinase (SFK) inhibitor. In conclusion, activation of $\alpha 7$ by ZP leads to SFK-dependent EGFR activation, Ca^{2+} influx, and the acrosome reaction.

The most characterized mouse sperm protein that possesses specific binding for ZP3 is the protein sp56, however this protein presents in the acrosomal matrix, not in the sperm PM. A more recent study reveals that ZP3R/sp56 is not essential for mouse fertilization. Moreover, mouse sperm begin to undergo AR in the upper isthmus of the oviduct, thus the acrosomal content including sp56 is spread out from the sperm far away from the egg ZP. Interestingly, the group of Yanagimachi shows that only a few sperm cells migrate from the isthmus to the ampulla during the progression of fertilization suggesting that it is quite difficult for acrosome-reacted sperm to migrate from the isthmus to the ampulla.

Another candidate that has been implicated as a receptor for ZP3 in mouse sperm is a specific form of β -galactosyltransferase (GalTase). It has been postulated that GalTase mediates sperm-ZP binding by interacting with ZP3 oligosaccharide residues, leading to activation of the heterotrimeric Gi-protein. However, targeted mutation of the GalTase gene yields fertile null males, yet their sperm bind less ZP3 than WT and are unable to undergo a ZP3-induced AR. Thus, it was concluded that GalTase is not absolutely critical for fertility.

In conclusion, although several research groups suggested a number of sperm proteins as candidates that mediate sperm-ZP binding, it is not clear yet which sperm protein is indeed necessary for this binding. Moreover, the fact that mouse sperm, which undergo AR before interacting with the egg, are fertile raises the question if indeed we will find a sperm ZP-receptor protein that is absolutely critical for fertilization (Fig. 1).

Intermediate Stages and Spontaneous Acrosome Reaction

Although AR is a precise well-regulated exocytotic process, spontaneous AR (sAR) can occur under some conditions. Sperm samples with high proportion of sAR result in poor success of fertilization. Therefore, sperm contain mechanisms that protect them from undergoing sAR. Ca^{2+} /calmodulin-dependent protein kinase II (CaMKII) protects mouse sperm from undergoing sAR by interacting with MUPP1. Inhibition of CaMKII in bovine sperm during the incubation under capacitation conditions strongly induces sAR. We showed that actin polymerization occurs during mammalian sperm capacitation, and the formed F-actin should be dispersed prior to the AR. The process of actin polymerization is mediated by two distinct pathways: the PLD-pathway and the CaMKII-pathway. Actin polymerization during sperm capacitation protects the sperm from undergoing sAR. Thus, activation of PLD and/or CaMKII during sperm capacitation is essential for preventing the occurrence of sAR.

Many studies show that sperm representing intermediate stages of fully and partially acrosome reacted cells. Four basic patterns were discovered in mouse and guinea pig sperm, and six in human sperm. It was also shown that few morphological and biochemical steps of hybrid vesicle formation occur prior to complete the AR. It is concluded that sAR is not a synchronous process.

VE	Vitelline envelope
ZP	Zona pellucida
ZPD	Zona pellucida domain

Outline

This article describes the nature, synthesis, secretion, assembly, structure, and function of the unique proteins that make up the mammalian egg's extracellular coat, the zona pellucida (ZP). Mention also is made of other vertebrate egg-coat proteins, location and expression of ZP genes, and evolution of ZP proteins.

The Mammalian Egg's ZP

The ovum or unfertilized egg is the link between one generation and the next. It is the process of oogenesis in females that is responsible for production of unfertilized eggs (Albertini, 2015). During oogenesis primordial germ cells generated in the fetus become mitotic oogonia, enter meiosis and become oocytes, achieve full-growth in the ovary, undergo meiotic maturation, are ovulated, and become unfertilized eggs.

All mammalian eggs and preimplantation embryos are completely surrounded by an extracellular matrix (ECM) called the zona pellucida (ZP) (Fig. 1) (Litscher and Wassarman, 2015). The thickness of the ZP varies from < 1 to > 20 μm depending on the species (Table 1) and plays vital roles in vivo during oogenesis, fertilization, and preimplantation development in mammals. For example, the presence of a ZP is required in vivo for normal production of Graafian follicles by the ovary, species-restricted fertilization of ovulated eggs by sperm, and maintenance of intact cleavage-stage embryos in the reproductive tract. Removal of the ZP from eggs results in direct exposure of the egg's plasma membrane to sperm and permits sperm from heterologous species to fertilize eggs (Table 1).

The ZP appears during oogenesis as an extremely thin ECM around oocytes that have begun to grow and increases in thickness as oocytes increase in size (Table 1). For example, mouse oocytes grow > 300-fold in volume, from about 12 to 80 μm in diameter, over 2–3 weeks and at the same time the ZP thickens to about 6.5 μm in width. The ZP consists of long, crosslinked fibrils that make up an elastic, relatively porous ECM that is penetrable by large macromolecules such as antibodies and even by small viruses. The innermost fibrils are oriented radially to the oocyte's plasma membrane and are closely packed, whereas the outermost fibrils are oriented tangentially and are more loosely packed. Following fertilization of ovulated eggs, preimplantation embryos at the expanded-blastocyst stage hatch from their ZP using protease(s) and then implant in the uterus.

ZP Proteins

The mammalian ZP is composed of either 3 (e.g., mouse and cow eggs) or 4 (e.g., rat and human eggs) glycosylated proteins, called ZP1–4, depending on the species (Wassarman, 2008; Litscher and Wassarman, 2015). ZP2 and ZP3 are monomers and ZP1 and ZP4

Fig. 1 Light and electron microscopic images of mouse sperm bound to the ZP of unfertilized eggs. Shown are Nomarski differential interference contrast (*top*) and transmission electron microscopic (*bottom*) images. In the bottom panel is a thin section of a sperm head with an intact acrosome (a) bound to the fibrillar ZP of an unfertilized egg. ZP, Zona pellucida; pm, plasma membrane.

are dimers of identical polypeptides connected by intermolecular disulfides. It has been suggested that ZP proteins have properties similar to those of amyloids that self-aggregate and form cross- β sheet fibrillar structures.

All ZP proteins are synthesized as precursor polypeptides that are processed into the mature polypeptides present in the ZP (Table 2). ZP1 and ZP4 are related to one another and have a 45 amino acid sequence, called a P or trefoil domain, that has 6 cysteine residues linked as 3 intramolecular disulfides. ZP2 and ZP3 assemble via non-covalent bonds into long fibrils that are crosslinked by ZP1 and/or ZP4 into a porous ECM. ZP fibrils exhibit a structural repeat due to the presence of a ZP2–ZP3 dimer every 14–15 nm.

Both ZP2 and ZP3 must be present during oogenesis to assemble a ZP. Female mice that are heterozygous-nulls for ZP3 (ZP3^{+/-}) assemble a ZP around oocytes/eggs that is about one-half its normal width, but the mutant mice are as fertile as wild-type mice. On the other hand, female mice that are homozygous-nulls for either ZP2 (ZP2^{-/-}) or ZP3 (ZP3^{-/-}) fail to assemble a ZP around oocytes/eggs and are infertile. Female mice that are homozygous-nulls for ZP1 (ZP1^{-/-}) assemble an extremely porous ZP around oocytes/eggs and exhibit significantly reduced fertility compared to wild-type mice.

Table 1 Approximate dimensions of mammalian eggs and their zona pellucida

Mammal	Egg-diameter (μm)	ZP-width (μm)	Ratio
Platypus	4000	1	4000:1
Possum	230	6	38:1
Mouse	80	6	13:1
Rabbit	125	15	8:1
Cow	120	16	7:1
Pig	130	16	8:1
Baboon	—	13	—
Human	120	22	5:1

Table 2 Size of zona pellucida polypeptides^a

<i>Mammal</i>	<i>ZP1</i>	<i>ZP2</i>	<i>ZP3</i>	<i>ZP4</i>
Platypus	(404) ^b	(700) ^b	403	(593) ^b

Human	638	745	424	540

^aNumber of amino acid residues per polypeptide (for references see [Litscher and Wassarman, 2015](#)).

^bOnly incomplete N- and C-terminal sequences are available.

^cZP4 is a pseudogene in mice.

^dZp1 is a pseudogene in cows and dogs; ZP1 has not been found in pigs.

Location and Expression of ZP Genes

ZP proteins are encoded by single-copy genes located on different chromosomes ([Wassarman, 2008](#); [Litscher and Wassarman, 2015](#)). In mice ZP1–ZP3 are located on chromosomes 19, 7, and 5, respectively. In humans ZP1–ZP4 are located on chromosomes 11, 16, 7, and 1, respectively. ZP genes are expressed coordinately and exclusively by growing oocytes making it female-specific gene expression. The number of copies of ZP messenger-RNA (mRNA) per oocyte or egg increases from undetectable levels (<1000 copies) in non-growing oocytes, to hundreds-of-thousands of copies in mid-stage growing and fully-grown oocytes, to almost undetectable levels (<1000 copies) in oocytes that undergo meiotic maturation and become unfertilized eggs. ZP mRNA also is undetectable in cleavage-stage embryos. During oocyte growth in mice the absolute rate of protein synthesis increases about 40-fold overall, with ZP synthesis representing about 5% of the total.

Conservation of ZP Proteins

ZP2 and ZP3 from different mammals, from monotremes and marsupials to placental mammals, are well conserved, exhibiting about 65%–99% identity. ZP1 and ZP4 exhibit only about 40% identity ([Litscher and Wassarman, 2014, 2015](#)). It has been suggested that proteins with sequence identities of 40% or more perform the same function and those with identities of 25%–40% perform similar functions. ZP proteins have several regions in common (“**Secretion and Assembly of ZP Proteins**” section), such as a signal sequence (SS), ZP domain (ZPD), external and internal hydrophobic patches (EHP, IHP), consensus furin cleavage-site (CFCS), and transmembrane domain (TMD), suggesting they may be derived from a common ancestral gene, perhaps the ZP3 gene, >500 million years ago. This gene duplicated several times during evolution and gave rise to 5 genes in amphibians, 6 genes in birds, and 3–4 genes in mammals. Many fish have 2–4 ZP genes, whereas some fish (e.g., zebrafish) have multiple copies or tandem repeats of ZP1 and ZP3 genes.

Other Vertebrate Egg Coats

It is relevant to note that fish, frog, and bird eggs also have an ECM surrounding them, called the vitelline envelope (VE), that consists of proteins highly related to ZP1–ZP4 ([Litscher and Wassarman, 2014, 2015](#)). The frog and bird egg VE consists of 4–6 proteins, called ZP1–ZP4, ZPd, and ZPax, and for many fish eggs the VE consists of 2–4 proteins, called ZP1, ZP3, ZPax, and variants of ZP1 and ZP3. ZPax is found in a few mammals, but is always present as a pseudo-gene. In fish and birds VE proteins are synthesized by both the ovary and liver, whereas in frogs, as in mammals, they are synthesized only by the ovary.

The ZP Domain

Primary structures of ZP proteins from mammalian eggs have been determined over the past three decades. A hallmark feature of all ZP proteins is an approximately 260 amino acid sequence, containing 8 conserved cysteine residues present as 4 intramolecular disulfides, that is called the ZPD ([Jovine et al., 2005](#); [Litscher and Wassarman, 2015](#)). The ZPD arose >600 million years ago and is found in hundreds of proteins in a variety of animal species, from invertebrates to vertebrates, and in a wide variety of tissues

and organs. These proteins include secreted proteins that function as receptors or mechanical transducers between adjacent cells, as intermediators during differentiation, morphogenesis, and signaling, or as proteins of ECMs other than egg-coats.

The ZPD is a bipartite structure consisting of an amino (N)-terminal subdomain (NTS) and a carboxy (C)-terminal subdomain (CTS) separated by a short protease-sensitive region. The two subdomains are always found in the sequential order NTS → CTS and never CTS → NTS, although the NTS, but not the CTS, is found in some proteins in the absence of a CTS (e.g., Oosp1, Plac1, and papillote). Proteins possessing a ZPD form polymers and isolated ZPDs on their own can polymerize into fibrils, with the NTS, not the CTS, responsible for polymerization. Divergent copies of the NTS are found in single or multiple copies in the amino-terminal regions of ZP1, ZP2, ZP4, and ZPax. Mutation of ZPDs, especially the NTS, can lead to severe pathologies, such as deafness, cancer, and possibly infertility.

Three-Dimensional Structure of ZP Proteins

The three-dimensional structure of the ZPD has been determined by X-ray crystallographic analysis of the (i) NTS of mouse ZP3 at 2.3 Å resolution, (ii) full-length chicken ZP3 at 2.0 Å resolution, (iii) protease resistant core (amino acid residues 295–610) of human uromodulin, a ZPD protein, at 3.2 Å resolution, and (iv) CTS (amino acid residues 463–664) of mouse ZP2 at 2.25 Å resolution. These analyses revealed that both the NTS and CTS adopt an immunoglobulin (Ig)-like fold consisting of an antiparallel sandwich of 2 β-sheets made up of 8 strands of polypeptide (strands A, B, D, and E and C, E', F, G; ≈ 50% of amino acid residues are in β-strands) that enclose a hydrophobic core, with 2 buried disulfides that clamp both sides of the sandwich (Monné and Jovine, 2011). The NTS of mouse ZP3 has approximate dimensions of 52 × 29 × 28 Å. In ZP3 crystals, two ZP3 molecules are arranged as homodimers in antiparallel orientation to form an asymmetric structure. The two ZPDs are bonded by electrostatic interactions between the NTS and CTS of opposing molecules; that is, NTS1:CTS2 and NTS2:CTS1. On the other hand, there are no NTS1:NTS2 or CTS1:CTS2 contacts within the homodimer. However, certain structural features make the ZPD distinct from other known Ig-like domains, such that it is a new Ig superfamily subtype structure. The NTS and CTS of uromodulin are similar to those of ZP3, having the same fold, disulfide connectivities, and a conserved tyrosine residue in the NTS; mutation of this residue in tectorin, a ZPD protein, is associated with hearing loss.

Secretion and Assembly of ZP Proteins

Certain sequence elements involved in secretion and/or assembly of nascent ZP proteins are located near their amino- or carboxy-terminus (Wassarman and Litscher, 2013) (Fig. 2). (i) One sequence element is an SS located at the amino-terminus that targets nascent ZP proteins to the secretory pathway where the SS is removed. The SS is removed during transit of nascent protein from the oocyte's endoplasmic reticulum to the Golgi. (ii) A second sequence element is an EHP located near the carboxy-terminus that interacts with an IHP located within the ZPD. The EHP–IHP interaction locks the ZPD in a conformation that is incompatible with polymerization, thereby preventing ZP protein assembly into fibrils within growing oocytes. Such coupling between proteolytic processing and polymerization is conserved by many or all ZPD proteins. (iii) A third sequence element is a TMD located

Fig. 2 Diagram of the precursor (*top*) and processed (*bottom*) mouse ZP2 polypeptides. ZP2 serves as an example of the four ZP polypeptides, ZP1–4, found in the ZP of eggs from different mammals. Precursor and processed ZP2 polypeptides consists of 713 and 599 amino acids, respectively. Illustrated at the top are the signal-sequence (SS), ZP domain (ZPD) consisting of an N-terminal and C-terminal subdomain (NTS and CTS, respectively; indicated by a red border), consensus furin cleavage-site (CFCS), and transmembrane domain (TMD). Also shown are the three extra copies of the N-terminal subdomain (NTS) of the ZPD located at the N-terminus of the ZP2 polypeptide [note: ZP3 polypeptide does not have extra copies of the NTS at its N-terminus]. After proteolytic processing at the CFCS the mature polypeptide (*bottom*), lacking the SS, CFCS, TMD, and short C-terminal sequence is incorporated into the ZP. ZP1 and ZP4 also have a trefoil domain, consisting of about 45 amino acids with 3 intramolecular disulfides, N-terminal to the ZPD. N, amino-terminus; C, carboxy-terminus. For additional information see Litscher and Wassarman, 2015.

at the carboxy-terminus that anchors nascent ZP proteins in secretory vesicles and plasma membrane. (iv) A fourth sequence element is a CFCS that is cleaved by a pro-protein convertase so that secretion of nascent ZP proteins takes place.

Within growing oocytes nascent ZP proteins are localized to secretory vesicles that originate from the trans-Golgi and these vesicles fuse with the oocyte's plasma membrane. The oocyte's Golgi is an important site of processing of secretory proteins and it expands dramatically in growing oocytes from flattened stacked lamellae in non-growing oocytes to swollen stacked lamellae associated with numerous vacuoles in fully-grown oocytes. Cleavage of ZP proteins at their CFCS takes place at the oocyte's plasma membrane and results in release of the proteins into the extracellular space. The processed, mature proteins then assemble on the innermost surface of the thickening ZP.

ZP Proteins and Fertilization

Fertilization of mammalian eggs occurs shortly after they are released or ovulated from the ovary into the reproductive tract. There is reason to believe that the ZP plays a role in species-restricted fertilization in mammals in much the same way as the VE restricts interspecies fertilization in some non-mammalian animals. Sperm bind to the ZP of unfertilized eggs and both ZP2 and ZP3 act as sperm receptors (Bleil and Wassarman, 1980; Avella et al. 2013; Florman and Fissore, 2014; Bianchi and Wright, 2016).

Mammalian sperm have an organelle derived from Golgi, called the acrosome, overlying their head (acrosome-intact/AI-sperm) (Fléchon 2016). To penetrate the ZP sperm must undergo the acrosome reaction (AR), a form of cellular exocytosis. This involves fusion of plasma membrane with outer acrosomal membrane and results in exposure of inner acrosomal membrane and its associated enzymes (acrosome-reacted/AR-sperm). Bound sperm are able to penetrate the ZP due to the action of one or more of these enzymes and to forward thrust of the sperm due to flagellar hyperactivity.

AI-sperm bind to ZP3 and AR-sperm bind to ZP2 of unfertilized eggs (Bleil and Wassarman, 1986; Avella et al., 2014; Wassarman and Litscher, 2016). Whereas binding of AR-sperm to ZP2 is due only to its polypeptide, binding of AI-sperm to ZP3 is due to its polypeptide and carbohydrate; the latter binding leads to induction of the AR. The region of ZP3 to which sperm bind is called the sperm combining-site (SCS) and it is a site of positive Darwinian selection perhaps having to do with species-restricted fertilization. It is possible that selective pressure drives the mutations in the SCS and thereby promotes divergence and evolution of ZP3. Following fertilization of eggs sperm can no longer bind to either ZP2 or ZP3 thereby contributing to prevention of polyspermy.

Glossary

Acrosome exocytosis The outer membrane of the acrosome, a subcellular organelle in the sperm anterior, fuses with the overlying plasma membrane to release its contents.

Cumulus oophorous Matrix rich in hyaluronic acid interspersed with cumulus cells that surrounds ovulated eggs in the oviduct.

Capacitation Sperm develop the capacity for acrosome exocytosis and hyperactive motility in preparation of fertilization.

Preimplantation development Following fertilization, the 1-cell (1C) zygote undergoes 3 cell division after which it compacts to form the morula (8-12C) and develops into a blastocyst with a fluid filled blastocoel which implants on the wall of the uterus.

Uterotubal junction The narrow passage through which sperm pass from the uterus to the oviduct.

Introduction

At birth, mammals have their complete complement of female germ cells which are arrested at the diplotene stage of the prophase of the first meiotic division. This arrested state, known as the dictyate, persists until just prior to ovulation and, depending on the oocyte, lasts weeks in mice and years in humans. Perinatally, granulosa cells cull out individual oocytes from a cluster to form primordial follicles in which the central germ cell is surrounded by flattened granulosa cells. From this resting pool of germ cells, cohorts, the size of which vary among mammals, are selected to enter a growth phase during which the zona pellucida proteins are secreted to form an extracellular matrix. Zona proteins are no longer produced in transcriptionally inert, fully grown oocytes which precludes further accretion of the zona matrix. During subsequent meiotic maturation and cumulus expansion in ovulatory (Graafian) follicles, a perivitelline space develops between the inner aspect of the zona pellucida and the egg plasma membrane.

Although tens of million sperm are deposited in the lower female reproductive tract at the time of coitus, relatively few (<10/egg) encounter ovulated eggs in the ampulla of the oviduct. Sperm initially ascend the female reproductive tract with linear, progressive motility characterized by low-amplitude, symmetric flagellar beating. Following penetration of the uterotubal junction, sperm accumulate in storage reservoirs in the oviduct isthmus by binding with their heads to the epithelial lining. Sperm undergo capacitation, an incompletely understood process, and the flagellar beat of sperm becomes asymmetric and develops high amplitude which facilitates release from the epithelium of the oviduct and assists in penetration of the investments that surround ovulated eggs. First, the hyperactive sperm encounters the viscoelastic hyaluronan of the cumulus oophorous in the ampulla of the oviduct. After penetrating the cumulus matrix, the sperm bind and penetrate the zona pellucida surrounding ovulated eggs. At some point during passage of the female reproductive tract, sperm undergo acrosome exocytosis and only acrosome-reacted sperm can fuse with the egg.

After fertilization, waves of calcium activate the egg which results in an effective block to polyspermy. There is an immediate block at the egg plasma membrane and additional sperm cannot fuse with the egg. This block requires gamete fusion and does not occur after fertilization by intracytoplasmic sperm injection. The calcium waves in the egg prompt cortical granule exocytosis which provides a potent block to sperm penetration through the zona pellucida matrix by mechanisms yet to be determined. Most importantly, cortical granules release lytic enzymes which modify the zona matrix to prevent sperm binding and provide a definitive block to polyspermy (i.e., if sperm do not bind to the zona surface, they cannot penetrate the zona matrix nor fuse with the egg plasma membrane).

The zona pellucida also facilitates the passage of the embryo through the oviduct. The preimplantation embryo divides within the confines of the zona pellucida during cleavage-stage development and formation of the morula. As the blastocyst forms, the zona pellucida thins and eventually the embryo hatches from the zona matrix leaving a ghost matrix behind. Whether this escape is purely mechanical or is assisted by enzymatic digestion remains unclear. Thus, the zona pellucida plays critical roles in fertilization, the postfertilization block to polyspermy and protecting the embryo prior to implantation.

In this article, we will review the biogenesis of the zona pellucida and its function during fertilization and preimplantation development using research focused on mouse and human model systems.

Biogenesis of the Zona Pellucida

Among mammals, the zona pellucida is composed of three or four homologous glycoproteins with varying designations that we have simplified to ZP1, ZP2, ZP3, and ZP4 based on mouse and human nomenclature. The human zona pellucida is encoded by four zona genes, but mouse *Zp4* is a pseudogene and the mouse zona pellucida contains only ZP1, ZP2, and ZP3 proteins. Each zona protein has a signal peptide at its N-terminus that directs it into the lumen of the endoplasmic reticulum and a transmembrane domain near its C-terminus that tethers it to the lipid bilayer during passage through the endomembrane system (Fig. 1A).

Each zona protein contains a ~260 amino acid bi-partite (N- and C-domains) zona module near the C-terminus. Based on conserved disulfide bond formation, two isoforms of the domain have been defined. One isoform, specific for ZP3 has a longer (44–45 amino acid) extension C-terminal to the zona module and the other isoform, specific for the remaining zona proteins has a shorter (0–5 amino acid) extension. It appears that at least one of each isoform is required to form a zona matrix. The structure of the N- and C-portion domains as well as the complete zona module of the chicken homologue of ZP3 have been solved by X-ray crystallography. Based on these results, a model has been proposed in which proteolysis at the maturation cleavage site (MCS) uncovers a hydrophobic patch on the C-ZP domain which promotes polymerization of the zona matrix in the extracellular space (Han et al., 2010).

Initially, the zona matrix is observed as discrete electron-dense clumps by electron microscopy that fill in during oocyte growth such that the fully-grown mouse (80 μm diameter) and human (120 μm diameter) eggs have 7 μm and 15 μm thick zonae pellucidae, respectively (Fig. 1B and C). By high resolution confocal and scanning electron microscopy, the zona pellucida appears as a porous sponge through which sperm must penetrate to fertilize the encased egg. Using mouse genetics, individual zona genes have been ablated. Mice lacking ZP1 form a zona pellucida that is thinner than normal and egg-free zona ghosts are observed in the oviduct with a concomitant decrease in fecundity. A more severe phenotype is observed in the absence of ZP2 in which a very thin zona matrix is observed during oocyte growth, but no zona pellucida is present surrounding eggs in preovulatory follicles. In the absence of ZP3, no matrix is formed at all and the zona-free eggs lacking either ZP2 or ZP3 are quickly resorbed into the epithelial lining of the oviduct after ovulation rendering female mice sterile (Fig. 2A). A frameshift that resulted in a truncated isoform of human ZP1 in a consanguineous family caused primary infertility in four sisters was reported as a potential dominant negative mutation that prevents formation of the zona pellucida matrix by premature aggregation of zona proteins in oocytes (Huang et al., 2014).

Fig. 1 Human and mouse zona pellucida. (A) Single copy genes encode human (ZP1, ZP2, ZP3, ZP4) and mouse (ZP1, ZP2, ZP3) zona proteins. After processing and secretion, the mature proteins are 62%–71% identical between the two species and the absence of mouse ZP4 reflects a pseudogene. Each protein has a bi-partite zona module for polymerization. Yellow lines, cysteine residues. Circles, potential *N*-glycan attachment sites: red, glycan present; black, glycan absent; open, not determined. The number of amino acids is below each mature zona protein. (B) Schematic representations of human zona pellucida surrounding ovulated egg with human sperm at right. (C) Same as (B), but for mouse.

Fig. 2 Genetic ablation of mouse *Zp1*, *Zp2*, and *Zp3*. (A) Ovarian histology of growing (*top*) and preovulatory (*middle*) oocytes from wildtype, *Zp1*^{Null}, *Zp2*^{Null}, and *Zp3*^{Null} mice fixed in glutaraldehyde, embed in methacrylate, and stained with periodic acid Schiff reagent. *Arrows*, thin zona pellucida. Differential interference contrast (DIC) images of unfixed ovulated eggs from each genotype (*bottom*). (B) Hypothetical model of the insoluble zona pellucida (*top*) based on the mutant mouse lines in (A) in which ZP2/3 (*bottom, left*) and ZP1/3 (*bottom, middle*) can form zona matrices, but ZP1/2 (*bottom, right*) cannot. Although less abundant, ZP1 forms disulfide-bonded dimers thought to strengthen the zona pellucida.

Fertilization

Zona Pellucida Ligand

Early models of gamete recognition emphasized the potential role of O-glycans associated with ZP3 as the primary ligand in the zona pellucida for a sperm surface receptor with β -galactosyl transferase a proposed candidate (Fig. 3A). However, biochemical analyses did not detect the proposed O-glycans on mouse ZP3 (Boja et al., 2003) and mutation of the putative attachment sites did not affect fertility (Gahlay et al., 2010). In addition, mice remained fertile after conditional ablation of the gene encoding T-synthase involved in forming implicated core 1 and core 2 O-glycan in zona pellucida (Williams et al., 2007). Because of its abundance in human zona pellucida, sialyl-Lewis^x antigen was proposed as a zona ligand (Pang et al., 2011), but human sperm bind and penetrate “humanized” zonae pellucidae in the absence of the sugar (Avella et al., 2014). The identity of putative sperm surface receptor for the zona ligand remains elusive and genetic ablation of genes encoding candidate proteins does not cause infertility. Models of gamete guidance based on chemo- or thermotaxis have been proposed but mechanistic molecular details remain to be determined, although the CatSper channel has been implicated in rheotaxis (Fig. 3B).

More recently, using genetically modified mice in gain-of- and loss-of-function assays, the N-terminus of ZP2 has been proposed as the zona ligand for sperm binding (Fig. 3C). Capacitated human sperm bind to human, but not mouse, zonae pellucidae. In transgenic mice, individual human ZP1, ZP2, ZP3, and ZP4 proteins were expressed in the absence of the cognate mouse protein. Human sperm bound and penetrated a zona pellucida containing human ZP2 (huZP2), but not huZP1, huZP3 or huZP4 (Baibakov et al., 2012). Mouse sperm did not bind to a zona matrix lacking moZP2 and these mice were infertile in vivo. Using chimeric human/mouse ZP2 proteins expressed in mice lacking endogenous ZP2 as well as ZP2 peptide beads, the sperm binding domain was further defined as moZP2^{51–149} (Avella et al., 2014) and neither N- nor O-glycans in this region are required for sperm-egg recognition and fertility. ZP2 peptide-beads can decoy sperm and act as effective, long-term, reversible contraceptives (Avella et al., 2016).

Fig. 3 Models of gamete recognition on the surface of the zona pellucida. (A) In the glycan-release model, *O*-glycans attached to ZP3 act as zona ligands for sperm surface receptors. After fertilization, putative cortical granule glycosidase(s) remove the glycan to prevent sperm binding. (B) In the chemoattractant model, either chemo-, thermo- or rheo-attractants guide sperm to ovulated eggs and dissipation of the gradients after fertilization prevent polyspermy. (C) In the ZP2 cleavage model, sperm bind to the N-terminus of ZP2 which is cleaved after fertilization by ovastacin released by cortical granules to prevent sperm binding. Only the ovastacin–ZP2 cleavage model has been substantiated by mouse genetics.

Sperm Receptor

Although candidate cognate sperm receptors for the zona ligand have been proposed, their genetic ablation does not cause male infertility in the absence of disrupted spermatogenesis. A clue to the putative receptor's identity may lie in the acrosome status when sperm bind to the surface of the zona pellucida. The acrosome is a Golgi derived, subcellular organelle underlying the anterior surface of the sperm that undergoes exocytosis during fertilization. There is general agreement that acrosome-intact sperm ascend into the oviduct to fertilize ovulated eggs in the ampulla and only acrosome-reacted sperm are observed in the perivitelline space between the egg plasma membrane and the inner aspect of the zona pellucida. However, the precise location and trigger for acrosome exocytosis have been difficult to pin down and the functions of the released proteins are incompletely understood.

Early investigators proposed that acrosome exocytosis occurred before sperm encountered ovulated eggs in the ampulla of the oviduct. Recent observations in transgenic mice in which acrosome-reacted sperm penetrate the zona matrix and fertilize cumulus-intact eggs support this hypothesis as does recent *in vitro* and *in vivo* imaging (Hino et al., 2016). An alternative model in which exocytosis is induced by ZP3 at the surface of the zona pellucida has become less compelling with the observation that sperm remain acrosome-intact after binding to the zona matrix *in vitro*. A third model proposes that the fertilizing sperm undergoes acrosome exocytosis as it begins to enter the zona matrix which could account for the presence of acrosome ghosts observed on the surface of the zona matrix. Further investigations using transgenic mice, high resolution imaging and complementary *in vitro* and *in vivo* studies should provide more definitive answers in the future.

Where acrosome exocytosis occurs will help direct the search for the elusive sperm surface receptor that interacts with the zona matrix. If acrosome exocytosis occurs prior to encountering the zona pellucida, the sperm receptor for the zona ligand is likely to reside within the acrosome matrix or on the plasma membrane that remains after exocytosis. A caveat to this line of reasoning is that some acrosome proteins dramatically change their locations after exocytosis. If acrosome exocytosis occurs on the surface or during the initial penetration of the zona matrix, then a search of the intact sperm plasma membrane is more likely to be rewarding. The acrosome has a well-defined matrix that is auto-processed during exocytosis with release of some components (e.g., acrosin, a serine protease) and the retention of others (i.e., neuronal pentraxin 2).

Penetration Through the Zona Pellucida

The ability of sperm to penetrate the zona pellucida has been ascribed to the motility of hyper-activated sperm and to lytic enzymes released by acrosome exocytosis. In support of the first model, sperm specific calcineurin (PPP3CC) deficient spermatozoa with abnormal sperm motility caused by an inflexible midpiece are unable to penetrate the zona pellucida (Miyata et al., 2015). In the second model, sperm binding to ZP3 induces acrosome exocytosis which releases acrosin to establish a penetration slit for passage of sperm through the zona matrix. However, genetic ablation of *acrosin* does not prevent male fertility (Baba et al., 1994), ZP3 is no longer a compelling candidate for gamete recognition (Gahlay et al., 2010) and current literature supports

acrosome exocytosis occurring prior to sperm binding to the zona pellucida. Alternatively, the forceful propulsion of hyper-activated sperm may be sufficient to penetrate the zona pellucida and release of acrosome contents may modify the sperm surface to facilitate fusion with the egg plasma membrane at fertilization or have some other function.

Block to Polyspermy

Monospermic fertilization is critically important for successful onset of development and potent blocks to polyspermy are rapidly invoked following gamete fusion. There is a rapid block at the plasma membrane. Unlike other species, this block does not involve postfertilization changes in membrane voltage in mammals. Rather, Juno, a sperm receptor on the egg plasma membrane interacts with Izumo1 on the surface of sperm and both are essential for fertilization (Bianchi et al., 2014). After sperm egg fusion, Juno is reported to be released from plasma membrane of eggs which would prevent additional sperm from fusing to already fertilized eggs. Fertilization by intracellular sperm injection (ICSI) activates the egg and induces cortical granule exocytosis, but does not trigger a membrane block to sperm binding or fusion. Gamete binding and fusion are necessary for this block which suggests either a direct or indirect sperm contribution.

The zona pellucida also plays an important role in the postfertilization block to polyspermy. After gamete fusion and egg activation, peripherally located cortical granules (0.2–0.6 μm in diameter) approach and fuse with the egg plasma membrane to release their contents into the extracellular space. A pioneer component of the cortical granules is ovastacin, a ~ 47 kD zinc metalloendoprotease that cleaves ZP2 (Burkart et al., 2012). Using deletion mutations in vitro and in vivo, a 7-amino acid motif has been identified that is required to localize ovastacin in the peripheral cortical granules (Xiong et al., 2017). Fetuin B, a ~ 43 kD protease inhibitor produced in the liver and present in the circulation and follicular fluid, inhibits low levels of constitutively secreted ovastacin (Dietzel et al., 2013). However, the amount of ovastacin released during cortical granule exocytosis is thought to overwhelm this fragile defense and modify the extracellular zona pellucida.

Following fertilization, ovastacin cleaves mature mouse ZP2^{35–634} at ¹⁶⁶LA[↓]DE¹⁶⁹ near its N-terminus. Although the two fragments remain di-sulfide bonded, sperm no longer bind to the zona pellucida matrix which provides a definitive block to polyspermy. Thus, embryos derived from female mice either lacking ovastacin or possessing a mutant form of ZP2 that cannot be cleaved, support postfertilization sperm binding to the zona pellucida surrounding early embryos (Gahlay et al., 2010; Burkart et al., 2012). On the other hand, isoforms of ovastacin lacking a genetically defined localization motif are not present in peripheral cortical granules and the resultant premature cleavage of ZP2 profoundly decreases female fertility (Xiong et al., 2017).

Protection of the Early Embryo

There is no obvious biological imperative for order-specific gamete recognition among mammals that fertilize internally. There are many behavioral, environment and physiological barriers to cross-species mating and, although some (e.g., human) gametes are fastidious, others (e.g., rodents) are not. However, the zona pellucida is necessary to prevent resorption of ovulated eggs into the oviduct epithelium. Mice lacking ZP2 or ZP3 do not form a zona pellucida surrounding ovulated eggs which are quickly resorbed into the epithelial lining of the oviduct. Likewise, if the zona pellucida is biochemically removed from 1-cell to 8-cell embryos, they are quickly resorbed and only zona-free embryos that reach the morula stage or beyond have a reasonable chance of survival during preimplantation development.

As the preimplantation embryo divides, individual cells become smaller and the zona pellucida accommodates the cleavage-stage embryo. However, beginning at the early blastocyst stage, the zona pellucida begins to thin and, as the blastocoel fills with fluid, the mature blastocyst escapes from the confines of the zona pellucida to implant on the uterine wall. Non-mammalian vertebrates secrete enzymes from the astacin family of metalloproteases that have been implicated in hatching from the vitelline envelope. A trypsin-like activity and two serine proteases, Prss28 and Prss29 have been investigated as hatching enzymes in mice. However, their roles have not been definitively defined and escape from the confines of the zona pellucida may be mechanical as the late blastocyst outgrows the constraints of the zona pellucida or reflect sequential contractions observed in the hatching blastocyst (Niimura, 2003).

Conclusions

The mammalian zona pellucida is multifunctional in mediating gamete recognition, providing a postfertilization block to polyspermy and facilitating passage of the preimplantation embryo through the oviduct. The three or four zona protein traffic through the endomembrane system as independent proteins and, only after secretion, form the higher order, insoluble extracellular zona pellucida. Despite intense investigations in multiple species, the structure and function of individual zona pellucida proteins remain incompletely understood. Still needed is a detailed understanding of the supramolecular organization of the zona matrix. It is anticipated that improved imaging technologies and structural studies will help resolve the relationship and stoichiometry among the individual proteins within the zona pellucida.

More sophisticated understanding of the molecular basis of gamete recognition would be facilitated by identification of the long-elusive cognate sperm binding protein(s). The difficulty of its identification brings into question the certitude of its existence. Taking advantage of taxon-specific gamete recognition of mice and humans, candidates could be tested in transgenic mice expressing human ligands. Once the three-dimensional structure of the zona pellucida is known, investigations can be undertaken to determine the postfertilization changes that prevent sperm binding. This could involve biochemical, structural, and genetic studies that would determine the molecular basis of the postfertilization block to zona penetration. Lastly, it would be considerable interest to determine the molecular basis by which the blastocyst hatches from the confines of the zona pellucida at the time of implantation. These investigations into the molecular biology of the zona pellucida and its role in fertilization and early development should readily translate to medicine and provide human patients with better reproductive choices.

Fertilization in the Oviduct

Janice P Evans, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States

The process of fertilization unites the two gametes to create and initiate development of the embryo. However, even before the sperm and egg meet and come together to become one combined cell, there are a noteworthy number of preceding, preparatory events that must occur for each of the gametes. Just as a student has to take precalculus before calculus, or take basic chemistry before organic chemistry, the gametes in both the male and female have to undergo prerequisite steps in order for fertilization itself to be successful. This article will cover these necessary prerequisite steps for the gametes, and then will also address the merger of the gametes and the early steps that initiate embryonic development. This also will highlight how fertilization *in vivo* (i.e., in the oviduct) differs from fertilization *in vitro*. In addition to this overview, there is more detailed information on these events in other chapters of this volume.

The Oocyte's Preparations for Fertilization

Each oocyte develops in its own individual compartment in the ovary, known as the ovarian follicle (or simply "follicle" for short). Oocytes progress through meiosis in a very staggered fashion. Mammalian female gametes initiate meiosis in the fetal ovary, doing DNA replication and progressing through the stages of prophase I (leptotene, zygotene, and pachytene), ultimately to arrive and arrest at what will be an extended version of diplotene phase; this is called the dictyate stage, also known as the resting stage of meiosis. With this as the starting point, there are two things that must change with the oocyte in order for fertilization to occur: (1) the oocyte must leave the ovarian follicle and enter the oviduct (also known as the fallopian tube; specifically the ampulla region of the oviduct, the site where fertilization normally occurs); and (2) the oocyte must progress from this prophase I arrest through meiosis I to a second arrest at metaphase of meiosis II. (One exception to this are dogs and foxes, with oocytes that arrest in meiosis and get fertilized at metaphase I of meiosis.)

These two crucial changes of the oocyte are coordinated by actions downstream from luteinizing hormone (LH), the gonadotropin that triggers ovulation. LH binding to the LH receptor on granulosa cells surrounding the outer wall of the pre-ovulatory follicle (known as mural granulosa cells) induces production of a variety of molecules within the follicle, with one of the most significant being the small signaling lipid Prostaglandin E₂ (Duffy, 2015; Kim and Duffy, 2016). Through paracrine effects on somatic cells within the follicle, PGE₂ facilitates follicle rupture, allowing the oocyte to leave the ovarian follicle and transverse to the nearby ampulla of the oviduct. The oocyte is released from the ovarian follicle surrounded by its associated cumulus cells, as a *cumulus–oocyte complex* (COC).

The actions of LH also induce a cessation of the signaling that maintains prophase I arrest. During early stages of oogenesis and folliculogenesis, oocytes initially are not competent to exit from prophase I arrest. Oocytes develop this meiotic competence during later stages of oocyte growth and follicle development, and once oocytes achieve meiotic competence, signaling within the ovarian follicle keeps the oocytes arrested at prophase I (Jaffe and Egbert, 2017). This arrest of meiotically competent oocytes in preovulatory follicles is mediated by a protein called natriuretic peptide precursor C (NPPC, also known as C-type natriuretic peptide). NPPC is produced by the mural granulosa cells, then acts in a paracrine fashion, binding to its receptor on cumulus cells (the NPPC receptor is known as natriuretic peptide receptor 2, or NPR2). NPR2 has enzymatic activity as a guanylate cyclase that produces the secondary messenger molecule cyclic GMP (cGMP). cGMP is transferred from the cumulus cells to the oocyte through gap junctions, and cGMP in the oocyte inhibits the activity of an enzyme called phosphodiesterase 3A (PDE3A). PDE3A is an enzyme that degrades the secondary messenger molecule cyclic AMP (cAMP), and inhibiting this enzyme and keeping cAMP levels in the oocyte high is crucial for maintain prophase I arrest in meiotically competent oocytes. cAMP in the oocyte acts through the cAMP kinase protein kinase A (PKA), which phosphorylates several cell cycle regulatory proteins that mediate maintenance of the oocyte's prophase I arrest (Jaffe and Egbert, 2017).

When it is time for ovulation and thus for the oocyte to exit from this prophase I arrest, the actions of LH reverse this entire process. This is achieved by several events within the follicle. Two components of this are LH causing both a decrease in NPR2 guanylate cyclase activity in cumulus cells and an increase in degradation of cGMP. These two actions decrease cGMP concentrations in cumulus cells, and in turn reducing the amount of cGMP in the oocyte (Jaffe and Egbert, 2017). In addition, LH binding to the LH receptor on mural granulosa cells leads to a new set of paracrine signals within the follicle, through the release of epiregulin and amphiregulin from the granulosa cells. These two proteins are ligands for epidermal growth factor receptors (EGFRs) present on the cumulus cells surrounding the oocyte. The binding of epiregulin and/or amphiregulin to cumulus cell EGFRs also appears to contribute to the decrease in cGMP (Jaffe and Egbert, 2017). An additional observed effect of LH in the preovulatory follicle is closure of gap junctions connecting closure of gap junctions connecting the cumulus cells to the oocytes, in turn terminating the transfer of cGMP to the oocytes (Jaffe and Egbert, 2017). The end result of all this is decreasing the amount of cGMP in the oocyte, which allows PDE3A to become active and to degrade cAMP. The decline in cAMP activity in the oocyte allows the oocyte to resume meiosis. The oocyte progresses from prophase I into meiosis I, and through cytokinesis (polar body emission), separating the homologous chromosomes. The sister chromatids remain together, and align as the meiotic spindle of metaphase II forms. The

ovulated oocyte in the oviduct is arrested at metaphase II, awaiting the signal from the sperm to complete meiosis (to be addressed below). The terms “metaphase II egg,” “MII egg,” or simply “egg” are sometimes used to describe the oocyte at this stage of meiosis.

The Sperm's Preparations for Fertilization

One obvious change that has to happen with the sperm is in location—the sperm has to be deposited in the female reproductive tract. But even before this, there are other crucial changes that the sperm has to undergo. Sperm complete meiosis during spermatogenesis in the seminiferous tubule of the testis (thus differing from how the female gamete undergoes meiosis). However, even though sperm isolated from the testis are haploid, these haploid sperm in the testis are unable to fertilize an egg. (The exception to this is when a sperm is injected into the egg cytoplasm through an assisted reproductive technology [ART] method known as intracytoplasmic sperm injection [ICSI].)

Two key steps of the sperm's preparations for fertilization occur while the sperm is still in the male, after the sperm has left the testes. The first of these is transit through the epididymis, with the sperm undergoing a process known as *epididymal maturation*. A crucial change that occurs during epididymal maturation is sperm become competent for progressive motility. Changes in sperm during epididymal maturation are thought to be mediated by several events, including sperm interactions with the epididymal epithelium, changes in the sperm surface proteome through acquisition of secreted proteins from the epididymal epithelium, and sperm acquisition of small vesicles released from the epididymal cells (exosomes or epididymosomes) (Gervasi and Visconti, 2017).

The second prerequisite step for the sperm occurring in the male is *mixture of the sperm with the semen*. Seminal plasma components are secreted by the epididymis and accessory glands of the male reproductive tract, the seminal vesicle, prostate, and bulbourethral gland (McGraw et al., 2015). In humans, the components of the semen are important for sperm to survive in the vagina and/or uterus (McGraw et al., 2015). The human vaginal environment is acidic, maintained in large part by the production of lactic acid by bacteria called lactobacilli. The acidic environment is beneficial for preventing certain vaginal infections, as the low pH will kill many types of microbes. However, the acidic environment will also kill sperm. Therefore, the buffering components of seminal fluid are essential to allow the sperm to survive deposition in the vagina. In some animal species that are induced ovulators (e.g., rabbits, camels), seminal plasma contains factors that induce ovulation (Adams and Ratto, 2013). There also are intriguing data that suggest that seminal plasma can affect the health of resulting offspring, based on experimental studies in mice comparing reproductive outcomes from males with and without seminal vesicles (Bromfield et al., 2014; McGraw et al., 2015).

After ejaculation, sperm then make their way through the female tract. The location of sperm deposition in the female tract varies between species (vagina, cervix, or uterus) (Gervasi and Visconti, 2016; McGraw et al., 2015). In humans, sperm travel from the vagina, through the cervix, into the uterus, and to region of the oviduct adjacent to the uterus, known as the utero-tubal junction (UTJ). It should be noted that the human cervix is hormonally primed during follicular phase of the menstrual cycle, such that the cervical mucus around the time ovulation is thin and watery, thus facilitating sperm passage through the cervix into the uterus. Data from a variety of studies, most notably of mouse knockout models, suggest that some process of sperm selection occurs in the female tract; the sperm from several specific knockouts fail to reach the UTJ, indicating that several sperm proteins have direct or indirect roles in successful transit to this part of the female tract (Gervasi and Visconti, 2016; Suarez, 2016).

It is in the female reproductive tract that sperm undergo their next important prerequisite step, *capacitation*, which is broadly defined as the process by which sperm acquire the capacity to fertilize. Capacitation in vivo is thought to be an extended, continuous process, beginning with ejaculation and continuing as sperm reside in the female tract. In the human, the peri-ovulatory cervical mucus may be part of the stimulus for the initiation of capacitation, with the uterine and oviductal environments continuing to support capacitation (De Jonge, 2017). Since the phenomenon of capacitation was first discovered, it has since been determined that capacitation can occur in vitro in certain chemically defined medium (Gervasi and Visconti, 2016). These discoveries and technological developments were part of what paved the way to making in vitro fertilization possible. Capacitation in vivo is mediated by a sequential series of cellular signaling events occurring in sperm as they travel up the female tract, central among them being signaling mediated by the second messenger molecule cAMP (Gervasi and Visconti, 2016). This signaling produces several biochemical changes in the sperm, which combine to culminate in capacitated sperm.

What is different about sperm that have undergone capacitation? The classic definition of capacitation means that the sperm now has the capacity to fertilize an egg, but there are specific changes observed as well, particularly with the later stages of capacitation. One of these is *hyperactivation of motility*. This is a distinct pattern of motility from the progressive motility acquired during epididymal sperm maturation (noted above), with hyperactivated motility characterized by high amplitude, asymmetric beating of the sperm tail (Suarez, 2008a). A key molecular player in hyperactivated motility is the multimeric ion channel known as Catsper, so named for its function as a cation/calcium channel on sperm. Catsper-mediated influx of calcium into the sperm tail drives hyperactivated motility. In human sperm, the activity of Catsper is stimulated by the steroid hormone progesterone, which is present in follicular fluid that is released with the cumulus–oocyte complex upon ovulation (Miller et al., 2015).

Another event associated with the later stages of capacitation is the exocytosis of a large vesicle on the head of the sperm, the *acrosome*. (Note: *Acrosome exocytosis* is also referred to as the *acrosome reaction*.) A long-time model for acrosome exocytosis is that the sperm binding the egg's coat, the zona pellucida (ZP), is the stimulus for acrosome exocytosis. Although there still is strong evidence for sperm interaction with the ZP, including in in vivo contexts (Avella et al., 2014, 2016), there is ongoing evaluation of the biology of acrosome exocytosis, including consideration of acrosome exocytosis in vivo being an event associated with

capacitation of sperm in the female tract (Gervasi and Visconti, 2016; Hirohashi, 2016). This is based on data from a variety of experimental studies (Inoue et al., 2011; Jin et al., 2011; La Spina et al., 2016), with the cautionary note that much of this is based on studies of mouse fertilization, and several aspects of sperm biology differ between species (De Jonge, 2017; Kaupp and Strunker, 2017). Setting aside the question of the physiological location of acrosome exocytosis in vivo, it should be emphasized that acrosome exocytosis is an important prerequisite step for fertilization. Acrosome exocytosis induces changes in the sperm surface, including remodeling and exposure of new surfaces of the sperm that render the sperm capable of binding and fusing with the oocyte plasma membrane (Cuasnicu et al., 2016; Hirohashi, 2016).

A related aspect of sperm residence in the female tract is the formation of *oviductal sperm reservoirs*, specifically in a region of the oviduct called the isthmus (Suarez, 2016). In most species, the establishment of this oviductal sperm reservoir is mediated by sperm binding to the epithelial cells that line the oviduct. The formation of oviductal sperm reservoirs is facilitated by a preceding step with the sperm, the mixture of sperm with semen. Proteins in the seminal plasma help to mediate sperm interactions with the oviductal epithelium (McGraw et al., 2015).

The formation of these oviductal sperm reservoirs is thought to contribute to reproductive success in several ways, including maintaining sperm viability and fertility, regulating capacitation and hyperactivation of motility, and helping to prevent polyspermic fertilization (fertilization of the egg by more than one sperm). Release of sperm from interactions with oviductal epithelial cells appears to be associated with later stages of capacitation and tied with signals with ovulation, although this is not fully understood (Gervasi and Visconti, 2016). Acquisition of hyperactivated motility appears to facilitate detachment of sperm from the oviductal epithelium (Suarez, 2016).

One practical implication of this in human reproductive biology is that these oviductal sperm reservoirs contribute to sperm being able to live in the female tract for several days (and in some species, sperm can live in the female tract for weeks and even months) (Holt, 2011; Suarez, 2008b). Sperm storage thus affects the fertile window that needs to be considered for fertility awareness-based methods of contraception. For example, if a woman has unprotected intercourse on a Monday and then ovulates 5 days later on Friday, this ovulated egg could potentially be fertilized by sperm residing in these reservoirs in her reproductive tract. Fertility awareness-based methods of contraception thus require that a woman abstain from intercourse or use a contraceptive (methods such as condoms, diaphragm, or spermicidal foams or creams) during the time frame in which sperm could survive in the female tract long enough to fertilize an egg that could be ovulated days later.

The Gametes in the Ampulla of the Oviduct

Following the release of sperm from the oviductal sperm reservoirs in the isthmus of the oviduct, sperm then make their way to the ampulla of the oviduct, the site of fertilization. Sperm first make contact with the oocyte's outermost coat, the cumulus layer (also called the cumulus oophorus). This layer contains cumulus cells, the somatic cells that surrounded the oocyte in the ovarian follicle, embedded in an extracellular matrix of hyaluronic acid. Hyperactivated motility facilitates penetration of this extracellular matrix, and there also is a possible role of a sperm-associated hyaluronidase activity, although this has not been conclusively demonstrated (Chang and Suarez, 2010; Hirohashi, 2016; Suarez, 2008a). The next extracellular coat that the sperm makes contact with is the zona pellucida (ZP). As noted above, there are ongoing questions about a sperm has to have an intact acrosome to interact with the ZP and whether the ZP serves as an in vivo agonist to trigger acrosome exocytosis (Buffone et al., 2014), but there are data that provide evidence of sperm–ZP binding (e.g., Avella et al., 2014, 2016). Hyperactivated motility plays a crucial role in sperm passage through the ZP to get the sperm to the space between the ZP and the oocyte plasma membrane, known as the perivitelline space.

Once in the perivitelline space, the sperm binds and fuses with the oocyte plasma membrane with the sperm protein known as IZUMO1 and the oocyte protein called Juno being essential for this process of the individual gametes merging to become the one-cell embryo (Yeste et al., 2017). Obviously one important part of the sperm that is delivered to the oocyte is the paternal DNA. In some species, sperm-provided centrioles may help mediate organization of the mitotic spindle for the first embryonic division (Clift and Schuh, 2013). However, even before embryonic mitosis is going to occur, the oocyte must exit from its arrest in metaphase of meiosis II, where it has been arrested since ovulation (see above). In addition, the oocyte has processes to prevent fertilization by additional sperm, known as blocks to polyspermy. These events are collectively known as *oocyte activation* (or *egg activation*), and are triggered by fertilization by the sperm.

Sperm–oocyte fusion results in cytoplasmic continuity between these two cells, allowing delivery of sperm components into the egg cytoplasm. In one of the earliest steps of this process, the sperm brings the factor that triggers the oocyte's completion of meiosis and initiation of embryonic development—the sperm-specific phospholipase C, PLC ζ , which plays a key role in (Clift and Schuh, 2013; Yeste et al., 2017). PLC ζ , like other phospholipase Cs, hydrolyzes the lipid phosphatidylinositol 4,5-bisphosphate (PIP $_2$) to produce two cleavage products, inositol 1,4,5-trisphosphate (IP $_3$) and diacylglycerol (DAG). IP $_3$ binds to the IP $_3$ receptor on the endoplasmic reticulum, which is an intracellular store for calcium ions (Ca $^{2+}$). The IP $_3$ receptor, with IP $_3$ bound to it, functions as a Ca $^{2+}$ channel, allowing Ca $^{2+}$ to be released from the endoplasmic reticulum to the oocyte cytoplasm. Once in the oocyte cytoplasm, calcium ions serve as the major driver of the oocyte-to-embryo transition, activating calcium/calmodulin-dependent kinase II γ (CaMKII γ) (Clift and Schuh, 2013). This kinase phosphorylates downstream substrates that lead to exit from metaphase II arrest, completion of meiosis, and progression to embryonic mitosis.

In addition to cell cycle resumption, another event of oocyte activation is the establishment of blocks to polyspermy. As noted above, IP₃ receptor-mediated release of calcium ions from the endoplasmic reticulum results in increased cytosolic calcium concentration. This calcium triggers exocytosis of vesicles known as cortical granules. A protease called ovastacin is released from the cortical granules, and this protease cleaves the ZP component ZP2, resulting in a form of the ZP that does not support sperm binding (Burkart et al., 2012). Calcium also appears to mediate the conversion of the oocyte plasma membrane to a form that is less supportive of sperm interaction (Gardner et al., 2007).

Conclusion

The events summarized here can be considered the culminating events of sexual reproduction, the process by which the gametes from two genetically distinct individuals come together to create new, genetically unique offspring. Gaining improved understanding of these central events of reproduction will advance our understanding of how reproduction can go awry, and result in subfertility or infertility. For example, a subset of men seen in infertility clinics have sperm with normal motility and morphology, and that can fuse with eggs, but the eggs fail to undergo egg activation. Research studies of these patients have revealed that sperm from some of these men lack functional PLC ζ (Kashir et al., 2011; Yoon et al., 2008). On the flip side, knowledge of how reproduction works will provide insights into ways to impair reproductive processes, and thus open the door to future methods of contraception. Several of the biological events noted in this article have been proposed to be potential targets for contraception. These include perturbation of ovulation by interfering with production of Prostaglandin E2 (Duffy, 2015), impairing the sperm's acquisition of hyperactivated motility with steroid-like molecules that act in an antagonistic fashion to progesterone (Mannowetz et al., 2017), and placing beads coated with ZP-like peptides in the uterus can serve as a "decoy" for sperm, causing sperm to fail to travel from the uterus to the oviduct (Avella et al., 2016). Research in this and other areas of reproductive biology is poised to produce discoveries that will lead significant advances for human reproductive health.

Decondensation of Sperm Chromatin

Glossary

Chromatin Complex of DNA and proteins that forms chromosomes within the nucleus of eukaryotic cells. DNA is condensed and wrapped around nuclear proteins (histones) to fit inside the nucleus.

Chromatin condensation Denser packaging of DNA in the spermatozoon, as a consequence of replacement of histones by protamines. In humans and other primates, 10%–15% of the sperm's genome remains packaged by histones thought to bind genes that are essential for early embryonic development.

Chromatin decondensation Process involving reduction of disulfide bridges of protamines, by glutathione and removal of protamines by a negatively-charged acceptor, thus allowing the formation of a histone-packed chromatin (nucleosome).

Glutathione (GSH) Important antioxidant in plants, animals, fungi, and some bacteria and archaea. Glutathione can prevent damage to important cellular components caused by reactive oxygen species such as free radicals, peroxides, lipid peroxides, and heavy metals.

Glycosaminoglycans Long unbranched polysaccharides formed by a repeating disaccharide unit, consisting of an amino sugar (*N*-acetylglucosamine or *N*-acetylgalactosamine) along with a uronic acid (glucuronic acid or iduronic acid) or galactose (except for keratan).

Heparin and Heparan sulfate Structurally similar glycosaminoglycans composed of two basic saccharides: *N*-acetyl-D-glucosamine or *N*-acetyl-D-galactosamine as the amino sugar and either D-glucuronic acid or L-iduronic acid as the uronic acid. These basic components are further modified by epimerization, sulfation, and deacetylation. Heparin is only produced by mast cells. It functions as an anticoagulant. Heparan sulfate is made by almost all cell types and has anticoagulant activity, but it is much lower than that of heparin. Heparan sulfate further varies from heparin in the degree of modification of the sugar residues.

Protamines Small, arginine-rich, nuclear proteins that replace histones late in the haploid phase of spermatogenesis; essential for sperm head condensation and DNA stabilization.

Spermatogenesis The process of male gamete production including formation of a diploid spermatocyte from a spermatogonium, meiotic division of the spermatocyte, and transformation of the four resulting haploid spermatids into spermatozoa.

Spermiogenesis Final stage of spermatogenesis, with differentiation of spermatids into mature, motile spermatozoa. Traditionally divided into: the Golgi phase, the cap phase, formation of tail, and the maturation stage.

Synergism An interaction between two or more drugs that causes the total effect of the drugs to be greater than the sum of the individual effects of each drug.

Syngamy The fusion of gametes resulting in the formation of a zygote, which develops into a new organism.

General Considerations

Evolution has devised a means to provide mammalian offspring with the best genetic parental traits, by separating a male and a female sex and, then, combining both genetic materials into a new cell, the zygote, which will develop into a genetically unique new organism. But this revolutionary way to select the best genetic material by choosing the most appropriate partner for the sexual encounter, has its caveats: fertilization occurs in a different organism than that where male gametes were formed.

The journey from the male gonads where spermatogenesis has taken place into the female body to reach the oocyte inside the Fallopian tube, where it resides after being ovulated from the ovarian follicle, has its risks and presents severe challenges to the tiny male germ cell.

The spermatozoon is a unique complex cell that originates from a spermatogonia in the seminiferous tubules of the testis and through spermatogenesis and spermiogenesis arises as a potentially highly motile cell, with a stack of mitochondria providing energy to its flagellum and keeping the genetic material inside a highly condensed nuclear chromatin. Although it is now known that sperm function does not end with the delivery of genetic material inside the oocyte, this is still considered to be its primary goal.

Reaching its destination is not an easy task for the spermatozoon. Although highly protected from the immune system inside the testis and mostly throughout its journey out of the male body, this protection ends when reaching the female counterpart. Physical and chemical barriers: rheological properties of vaginal mucus, pH changes, cells from the female immune system, a long distance to cover until it reaches the oocyte, are deadly threats for this cell for which keeping the genetic material as intact as possible is a must.

Chromatin Condensation

In any somatic cell, DNA is found packed as chromatin by its binding to positively charged proteins, histones, forming nucleosomes which provide not only spatial organization of the chromosomes but also a fine regulation of the dynamics of genetic information: chromosome duplication, gene transcription, genetic recombination, among other processes. However, this nucleosome organization does not provide the protection that sperm DNA requires to reach the fertilization site undamaged. Reactive oxygen species from male and female cells, as well as possible physical rupture from collisions along its journey are among the probable causes of DNA damage.

Sperm chromatin, in different species, is in a highly condensed state due to the removal of histones and their replacement by other positively charged, and smaller, proteins: protamines.

These proteins are arginine-rich, small proteins (50–110 amino acids) that contain multiple cysteine residues that are oxidized to form disulfide bridges both, intra and inter chain, linking protamines together. There are two protamines, P1 and P2. Spermatozoa from all mammalian species contain P1, while P2 is present in mice, hamsters, stallions, some primates and humans.

Protamine P1 is typically a 49–50 amino acids long protein, with a central arginine-rich domain (mainly responsible for binding to DNA) along with two flanking peptides containing cysteine residues. Protamine P1 and P2 seem to derive from a common precursor, but P2 has some characteristics that differ from P1, such as containing histidine residues. In humans, two processed forms of protamine P2 (P2 and P3) which differ in three amino terminal residues are often also found bound to DNA. After processing, approximately 40% of the amino terminus has been removed from P2. This final, processed form of P2, remains slightly larger than P1 (63 amino acids). Another difference between protamine P1 and P2 is that P2 is capable of binding zinc through coordination with its histidine and cysteine residues, forming zinc-fingers which participate in binding to DNA.

Spermatogenesis in humans is a continuous process, very precisely regulated and controlled, which results in the production of spermatozoa containing half the number of chromosomes (haploid) and potentially capable of fertilizing the oocyte (spermatozoa will achieve full capacity after maturation in the epididymis and capacitation in the female reproductive tract). The process of spermatogenesis can be divided into different phases: mitotic cell division with amplification of genetic material, a meiotic phase with reduction to half the number of chromosomes and a final phase known as spermiogenesis. Through these phases, haploidization takes place, as well as reorganization of genetic information within the germ cell. In the spermiogenesis phase, transcription stops as an integral part of germ cell differentiation, and chromatin remodeling takes place. The strong reorganization of chromatin involves gradual replacement of histones by protamines, through binding of testis-specific histones, then of transition proteins and, finally, as nucleosomes are removed, of protamines, generating a highly condensed sperm chromatin in the nucleus. However, the exact process of chromatin remodeling in sperm cells is still not fully comprehended.

In comparison to histone binding to DNA in the nucleosome, each protamine P1 binds to 10–11 bp of DNA, while protamine P2 binds to a larger segment of around 15 bp. This binding, through protamine positive charges, neutralizes the negative charge along the phosphodiester backbone of DNA, thus allowing a more compact packing of adjacent DNA molecules. Apparently, P1 wraps around the DNA helix in the major groove, with one protamine molecule per turn of DNA helix. Combination of hydrogen and electrostatic bonds of the guanidinium portion of the arginine molecule in protamine, provides an anchoring site for protamines and phosphate groups in both DNA strands. This gives rise to a toroidal and more densely packed chromatin. Considering that about 15% of histones remain in sperm chromatin, and the differential binding of protamine P1 and P2 to different stretches of DNA, it can be speculated that sperm chromatin will be packed in a non-homogeneous fashion which could be relevant when decondensation occurs.

Chromatin Decondensation

Decondensation is the first visible change that takes place inside the oocyte, once the spermatozoon has entered the ooplasm after binding to the oolema. The highly-packed, transcriptionally-inactive sperm chromatin needs to be unraveled and converted into a nucleosome-based chromatin, leading to the formation of the male pronucleus, before syngamy can occur.

In mammalian species, including humans, this chromatin decondensation seems to occur in two different stages: first the reduction of disulfide bonds in protamines and, then, replacement of these reduced protamines by oocyte histones. While there is no doubt on the role of oocyte reduced glutathione (GSH) as the reducing agent for protamine disulfide bonds, the nature of the protamine acceptor (the molecule that will compete with DNA for protamine binding and, in so doing allow for histone replacement and nucleosome formation) is still unknown. In fish, amphibians and *Drosophila melanogaster*, nucleoplamin (a pentameric acidic protein, considered to be the first identified molecular chaperone) has been shown to be the protamine acceptor and, thus, responsible for sperm nuclear decondensation. These findings have not been extended to humans and, for a while no evidence of the equivalent molecule was found.

It was shown that heparin (Hep) (a highly negatively charged sulfated glycosaminoglycan, best known for its anticoagulant properties), together with GSH could decondense human sperm chromatin in vitro, and proposed as a putative decondensing agent in vivo.

Since the only cell capable of synthesizing heparin in vivo is the mast cell, and no heparin has been found in the oocyte–cumulus complex, this was highly unlikely. However, evidence of the presence of other glycosaminoglycans (GAGs) in the complex, particularly heparan sulfate, structurally similar to heparin and with similar functions (other than anticoagulant) in different biological systems, led us to investigate the possible role of heparan sulfate (HS) as nuclear-decondensing agent in vivo.

Fig. 1 Nuclear decondensation of human spermatozoa, as visualized under phase contrast. U = unchanged, M = moderately decondensed, G = grossly decondensed. Original magnification $400\times$ (bar = $10\ \mu\text{m}$).

Using a decondensing mixture composed of GSH and different GAGs (heparin, heparan sulfate, dermatan sulfate, hyaluronic acid, or chondroitin sulfate) we determined that heparin and heparan sulfate had the highest (and similar) decondensing ability. Chondroitin sulfate and hyaluronic acid showed no activity at all and dermatan sulfate could decondense to a similar or lower degree than HS/Hep. The percentage of chromatin decondensation was determined by microscopic observation of sperm, using phase contrast light microscopy, according to the aspect of the sperm head: U (unchanged), M (moderately decondensed), or G (grossly decondensed) (Fig. 1).

Decondensation of human sperm chromatin occurs with freshly crushed murine oocytes in the presence of GSH, and is abolished in the presence of heparinase (enzyme that breaks heparan sulfate down to disaccharides). This is a clear indication of the presence and involvement of this GAG in sperm chromatin decondensation. Moreover, the presence of this glycosaminoglycan in the ooplasm was confirmed by immunocytochemistry using a specific antibody, in murine, bovine and human oocytes at various stages of maturation.

Contrarily to what has been usually accepted, the decondensation process seems to be a synergistic cooperation between GSH and heparan sulfate/heparin rather than a two-step mechanism where first the disulfide bonds of protamines are reduced by GSH and, then, the acceptor molecule (heparan sulfate) removes protamines from their association to DNA. The capacity of P2 to bind zinc ions explains the decondensation that occurs in vitro when EDTA (chelate forming agent that complexes divalent cations) is used in combination with heparin/heparan sulfate. The free thiol groups in cysteines, resulting from zinc removal, trigger the auto-reduction of protamine disulfide bonds, thus allowing the GAG to remove these proteins. So far, no transition proteins have been involved in this decondensation process.

When dermatan sulfate is used as decondensing agent instead of heparan sulfate, maximal decondensation achieved is lower, and in rodents, but not in humans, a synergistic effect is found when both GAGs are used together. These differences are an indication of a chromatin with different accessibility to both molecules. Heparan sulfate/heparin are highly-sulfated glycosaminoglycans whose molecules form a spiral-like helix, with their negative charges distributed in a fashion that resembles the DNA molecule with its negative phosphate groups pointing towards the periphery of the helix. On the other hand, dermatan sulfate is less sulfated, with a less ordered distribution of negative charges which creates a more homogeneous negative surface and, thus, quite different from a DNA-like distribution. These differences between both GAGs should influence the way each one interacts with sperm chromatin and could have its counterpart in decondensation. One could speculate that Hep/HS would provide a more DNA-like interaction and, thus, a better competition for protamines; while interaction with DS could be directed towards the remaining nucleosome-like, histone-rich, portions of sperm chromatin.

Chromatin Decondensation and Fertility

It is now well established that changes in protamine content or P1/P2 ratio result in diminished fertility both in humans and in rodents. Other than chromatin compaction/organization no function has been attributed to protamines in the sperm nucleus. It is likely that a lower or higher protamine content or altered protamine ratio will result in a differentially condensed chromatin and, as such, more prone to attack by reactive oxygen species and potential DNA damage. The possibility of analyzing sperm decondensation in vitro with two different GAGs (heparan sulfate and dermatan sulfate) allows for differential screening of possible alterations in chromatin condensation in semen samples from patients attending fertility clinics. Such studies could be relevant in those cases where the sperm nucleus remains condensed inside the oocyte following in vitro fertilization.

Polyspermy

Brian Dale, Centre for Assisted Fertilization, Naples, Italy

What Is Polyspermy

Animals may be classified into two major groups according to the kinetics of sperm–oocyte interaction. In the most commonly studied group, which includes sea urchins and mammals, only one spermatozoon normally enters the oocyte. If more than one spermatozoon does enter the oocyte then the multiple nuclei interact together leading to anomalous division—a term called pathological polyspermy. In other animals e.g., ctenophores, insects, elasmobranchs, some amphibians, reptiles and birds, it is normal for several spermatozoa to enter the oocyte cytoplasm. This is called physiological polyspermy. However, here only one male nucleus will interact with the female nucleus while the others degenerate. In a small minority of animals (about 0.1%) the problem of polyspermy does not exist since fertilization is parthenogenetic and development proceeds without the participation of the spermatozoon.

Our knowledge on fertilization has been obtained mainly from using models, such as the sea urchin and the mammal, that lend themselves to experimentation in the laboratory. Gametes from these animals are easily harvested and fertilization and early development are easy to follow *in vitro*. The text book images of oocytes in the laboratory deprived of their extracellular coats with thousands of spermatozoa attached to their surface are familiar and these led to the idea that a surface mechanism existed that allowed the entry of one spermatozoon while blocking the entry of supernumerary spermatozoa. In particular, two activation events, an electrical depolarization and the cortical reaction were suggested to be mechanisms that had evolved to prevent the entry of multiple sperm. The term polyspermy prevention was born and quickly adopted into the scientific vocabulary and this mystic mechanism of sperm exclusion extrapolated to many other animal groups. However, under natural conditions, contrary to what many think, the number of spermatozoa at the site of fertilization is extremely low, compared to the numbers generated. The sperm: oocyte ratio is regulated first by dilution, in externally fertilizing species, and the female reproductive tract in those with internal fertilization, followed by a bottleneck created by the oocytes extracellular coats, where only the fertilizing spermatozoon encounters and responds to the correct sequence of signals and enters the oocyte. Other spermatozoa are halted or slowed down by defective or sub-optimal signaling. Since under natural conditions, the final sperm–oocyte ratios approach unity it would appear that selective pressures have favored the achievement of monospermy, rather than the evolution of polyspermy preventing mechanisms.

Laboratory Experiments and the Sea Urchin Model

Marine invertebrate oocytes have been the model of choice for centuries owing to their abundance and amenability to laboratory conditions and manipulations, and the experimental animal par excellence is of course the sea urchin, favored by scientists of note such as Hertwig, Boveri and Herbst. Sea urchins are a member of the echinoderm family and are found globally. Animals are collected by divers often without taking into account their breeding patterns or sexual maturity. Gametes are obtained, either by injecting a concentrated salt solution into their body cavity or by manual dissection. The oocytes are surrounded by a jelly layer, that is indiscriminantly removed (by acid treatment) and these large cells are often attached electrostatically to slides to flatten them out, both for imaging or electrophysiological recording. Delage over 100 years ago showed that meiotic and cytoplasmic maturity in sea urchin oocytes is asynchronous leading to heterogeneous populations of oocytes. Although oocytes are effectively arrested at a specific point in the cell cycle, waiting for the activation signal from the spermatozoon to commence development, this metabolic block is not permanent and oocytes *in vitro* will activate spontaneously although at a slower rate than those activated by the spermatozoon. This is called aging and leads to the oocyte having an altered receptivity to spermatozoa, a condition that can be mimicked by treating oocytes with a variety of physical and chemical agents such as heat shock, nicotine and drugs that affect the actin cytoskeleton.

Images of sea urchin oocytes immersed in myriads of spermatozoa in a laboratory setting triggered the concept that fertilization, at least in these animals, was a haphazard “free for all,” analogous to a first order chemical reaction and that the first spermatozoon that successfully interacted with the egg triggered membrane mechanisms that blocked the entry of other spermatozoa. Today we are much more aware that scientific experiments need to be carried out under natural conditions and, in particular, to avoid manipulating oocytes and altering the characteristics of the cells before we start an experiment (Fig. 1).

The Kinetic Experiments of Lord Rothschild

Lord Rothschild and colleagues in the 1940–50s studied sperm–oocyte interaction in sea urchins at various concentrations and conditions and came up with the idea that the fertilizing spermatozoon induced a fast, yet partial, change in the oocyte surface that preceded the cortical reaction and that reduced sperm receptivity by 1/20th. Lord Rothschild made the assumption that a suspension of spermatozoa was analogous to an assembly of gas molecules, and calculated the number of sperm–oocyte collisions at various sperm concentrations. By mixing oocytes and sperm at known densities for varying periods of time and, by treating the

Fig. 1 The surface of a sea urchin oocyte. Are all the attached spermatozoa capable of entering the oocyte?

fertilization reaction as a first order chemical reaction, Rothschild found that the fraction of monospermic oocytes increased in time according to the relationship:

$$M(t) = 1 - e^{-\alpha t} \text{ below sperm densities of } 3 \times 10^6 \text{ per mL}$$

The relationship is similar for polyspermic oocyte at densities between 7×10^7 and 3×10^8 per mL giving a rate of appearance of polyspermic oocytes as α^1 . He argued that since α^1 (the refertilization rate) was found to be much less than α (the monospermic rate), a rapidly acting partial block reduced the probability of successful reactions after the first had occurred.

Although an exercise to be studied by all students of biology, the Rothschild Hypothesis has fundamental flaws: First, fertilization is not a first order chemical reaction and spermatozoa are not analogous to gas molecules. Second, it does not consider the possibility that there are a limited number of sperm entry sites on the oocyte surface. Lastly, it assumes that all spermatozoa are equal in their capacity to penetrate the cell. This is incorrect. Only competent spermatozoa that encounter and respond to the correct sequence of triggering events as they progress through the oocyte investments are successful.

Oocytes Are Programmed for Rapid Change

The oocyte and the spermatozoon are designed to trigger physiological changes in each other. In order to proceed through the layers of extracellular coats that surround the oocyte, the spermatozoon encounters a series of consecutive signals that induce changes in its physiology and are a pre-requisite for further progression. If one observes sperm–oocyte interaction in echinoderms or mammals with their coats intact it can be seen that many sperm are halted partially through their voyage. Once the spermatozoon has reached the oocyte plasma membrane, and probably following fusion of the two cells, this small cell (less than 500,000 smaller than the oocyte) triggers the quiescent oocyte into metabolic activity that eventually leads to meiotic resumption and formation of the zygote.

The first signs of oocyte activation are changes in the ion permeability of the plasma membrane and the entry and subsequent release of intracellular calcium. While the former maybe localized to the site of sperm entry, the latter starts at the entry site and spreads in an autocatalytic wave to the antipode. Simultaneously, and probably in conjunction, there is a massive re-organization of the cell cortex involving cytoskeletal elements and a cascade of cell cycle kinases. The length and density of microvilli, location of cortical granules, and the priming of the intracellular Ca^{2+} release mechanism are events in oocytes that are tightly controlled by the actin cortical cytoskeleton. In the starfish oocyte, the acrosome reaction can be seen to be induced at the outer layer of the jelly and a long tubule then grows from the tip of the spermatozoon to perforate the jelly and the vitelline coat to fuse with the oocyte plasma membrane. The successful spermatozoon needs to encounter a series of consecutive signals that induces changes in its physiology and are a pre-requisite for progression before triggering a localized sub-cortical polymerization of actin, beneath the fertilization cone, that is then involved in the movement of the spermatozoon into the oocyte. This successful sperm anchor site is regulated by the underlying actin cytoskeleton and, in any case, must be pre-determined.

At activation, the oocyte changes its role from a quiescent cell programmed to interact with its male counterpart, to a dynamic zygote that must be kick-started to progress through early development. The early embryo must be protected and isolated from its environment. Protection is afforded by the cortical reaction. Just below the surface of the sea urchin oocyte lie 20,000 granules each measuring about $1 \mu\text{m}$ in diameter containing a cocktail of enzymes and macromolecules. They release their contents into the perivitelline space, following interaction with the fertilizing spermatozoon, by fusing to the oocyte plasma membrane. Fusion starts at the site of sperm entry and then traverses the oocyte in a wave to the antipode taking about 30 s to complete. This leads to a net increase in the total surface area of the plasma membrane, which can be observed as a transient increase in length of microvilli.

The cortical reaction has evolved to change the receptive outer investment of the oocyte into a hardened protective layer to protect the developing embryo in the early stages of embryogenesis and to provide a microclimate for the early division cycles and morphometric movements.

Activation events are propagative, pre-determined and progress at a rate independent of sperm concentration. Thousands of biochemical and physiological pathways are triggered in a spatial and temporal pattern that does not lend itself to traditional molecular biological studies, such as depletion or over-expression of any particular component. These processes are not specific to gametes, but are biochemical and physiological processes common to all cells, however with different kinetics.

Studying Sperm–Oocyte Kinetics Using Electrophysiology

The experiments of Lord Rothschild were the first indirect attempt to measure the receptivity of the oocyte to spermatozoa. However, it was not until the 1970s that electrophysiological recording gave a precise picture of these kinetics. Sea urchin oocytes are large and transparent and easy to impale with microelectrodes to record electrical changes across the oocyte plasma membrane. Many spermatozoa attach to the oocyte, before one, the fertilizing spermatozoon, distinguishes itself by gyrating around its point of attachment. Approximately 3 s later, a small electrical step depolarization occurs, with no change in the morphology of the oocyte surface or sperm behavior, until a further 9 s later when a larger bell-shaped depolarization starts. The successful spermatozoon then stiffens, stops gyrating, and the cortical reaction is initiated at this point. A protuberance of the oocyte cortex (the fertilization cone) is formed and the sperm head slowly disappears into this cone, while the cortical reaction spreads across the oocyte to the antipode. The cortical reaction leads to the elevation of the fertilization membrane and is completed during the repolarizing phase of the fertilization potential. Unsuccessful spermatozoa, that is, those that do not enter the oocyte, attach to the oocyte surface, but do not generate either electrical step depolarizations or fertilization cones, and continue gyrating around their point of attachment for many seconds until their energy resources are depleted and fall limp to the oocyte surface. Thus progression of spermatozoa through the extracellular oocyte coats relies on them encountering and responding in sequence to oocyte borne signals. The successful spermatozoon, which may have pre-determined characteristics, completes this sequential pathway, the supernumerary spermatozoa fail at various stages falling to the wayside. In either case, the oocyte and its topographical organization selects the most fit spermatozoon. In physiological polyspermic species, such as the ctenophores, a parallel spermatozoon selection process by the oocyte occurs, but within the oocyte cytoplasm. In *Beroë* for example, which has a very clear large oocyte, several spermatozoa enter anywhere over the oocyte surface and remain immobile under the surface. The female pronucleus then starts to migrate around the oocyte surface progressively encountering several sperm pronuclei until it decides to fuse with the successful sperm pronucleus. It is not clear how this selection process is regulated however here, as with pathological polyspermy, the fertilizing spermatozoon distinguishes itself from supernumerary spermatozoa.

Fertilization Under Natural Conditions

Gametes vary enormously in form, function and numbers produced and accordingly there are many ways in which sperm–oocyte interactions are regulated.

Animals With Low Sperm Numbers

Contrary to popular belief not all animals produce large sperm: oocyte ratios. For example, in some insects and nematode worms sperm utilization is very efficient. In *Drosophila*, there is a 1:1 ratio between the progeny produced and the number of sperm in the seminal receptacles. In the nematode worm, *Caenorhabditis elegans*, every spermatozoon fertilizes an oocyte, however not all oocytes are fertilized because in fact oocytes are produced in excess. In about 0.1% of all animal species, reproduction is achieved without the participation of spermatozoa and this phenomenon is called parthenogenesis. There are many variations in the precise strategy of parthenogenesis. In aphids, for example, parthenogenetic generations alternate with those generated by fertilization and in bees an egg may be parthenogenetic or fertilized. The creation of female parthenogenetic offspring is widespread among insects such as some Phasmida, Diptera and Lepidoptera while in the crustacea, the best known example of parthenogenesis is the brine shrimp *Artemia salina*. Nematodes, rotifers, snails and flatworms also include a few parthenogenetic species, whereas in the vertebrates the most common form of parthenogenesis and female only species are found in the lizards.

Animals With High Sperm Numbers

In animals with high sperm numbers bottlenecks exist to reduce the number actually reaching the oocyte.

Reduction by elimination

Mammals are pathologically polyspermic and the sperm: oocyte ratio at origin can be as high as $10^9:1$. If we examine sperm size and number in relation to body mass in these animals it appears that evolutionary responses have favored sperm number rather than sperm size with increasing body size. Essentially, larger animals such as elephants, produce more sperm per ejaculate (corrected for

body mass) than a small mammal such as a mouse. Despite these large sperm numbers in the mammals, behavioral adaptations are required to ensure fertilization. Mating must be synchronized and the sperm need to be deposited in the female tract. In humans the spermatozoa are deposited in the vagina, while in mice they are deposited directly into the uterus. In both cases the vast majority of spermatozoa are rapidly eliminated from the tract. Only a minute fraction successfully migrate to the site of fertilization. The major barrier for sperm ascent in mice is the utero-tubal junction, with spermatozoa being progressively released from the lower part of the oviductal isthmus at ovulation. The first barrier to sperm ascent in humans, is the highly folded mucus filled cervix, where sperm are retained and released over a period of several days. Contractile activity of the uterine wall aids sperm ascension to the lower isthmus where they are sequestered until ovulation. Finally, migration from the isthmus to the ampullae appears to be due to sperm motility and contractile activity of the oviduct. In conclusion, in the mammals the number of sperm that reach the site of fertilization is regulated by the female tract. In the few *in vivo* studies where spermatozoa have been counted *in situ*, a few hundred spermatozoa were found in sheep ampullae and only five were found in man, while in rodents the sperm: oocyte ratios at the site of fertilization are usually unity or below.

In birds, which are physiologically polyspermic, hundreds of millions of sperm are inseminated, but only a few hundred reach the ovum, the vast majority are ejected by the female tract early after copulation. In the Zebra Finch and Domestic Fowl the female tract regulates the number of sperm reaching the site of fertilization and it has been suggested that although one or few spermatozoa are sufficient to activate the oocyte, the presence of several supernumerary spermatozoa in the cytoplasm of the oocyte is a pre-requisite for embryogenesis.

Dilution bottleneck

In marine animals, whether or not fertilization occurs at all depends on environmental cues, behavioral adaptations and chemotaxis. Sperm concentration in the sea urchin testis is similar to that in mammals, however many more oocytes are produced than in mammals, consequently the problem faced by these animals is making sure there are enough spermatozoa to satisfy all the oocytes spawned. In sea urchins, the sperm: oocyte ratio at source is $10^4:1$. When dealing with sea urchin gametes in the laboratory a sperm-oocyte ratio that leads to 100% fertilization at time 0, with minimum rates of polyspermy is often selected (10^6 per mL), however data collected from natural spawnings show a much lower fertilization rate and great variability in the proportion of oocytes fertilized in nature. Fertilization success in nature depends on the spawning behavior of the organisms, population size, current velocity, oocyte size, sperm swimming capacity and many other factors. The consensus from field studies is that fertilization success in free spawning benthic organisms can be $< 1\%$ and in any case is highly variable, ranging from 1% to 95%. Thus, in the environment, sperm-oocyte collisions are rare, sperm concentration may be extremely low (below 10^4 per mL) and the availability of sperm may affect female reproductive success. If, under natural conditions, sperm-oocyte collisions are indeed low, perhaps we should re-consider some of our ideas on the evolution of sexual dimorphism.

The egg coat bottlenecks

In all animals the oocyte is surrounded by complex extracellular layers or coats, which may be removed *in vitro* often without inhibiting fertilization. This is often erroneously interpreted as showing the inutility of the extracellular coats and is purely a laboratory artifact. In nature, passage through these coats is a pre-requisite for normal fertilization, oocyte activation and subsequent paternal nuclear de-condensation. Sea urchin oocytes are surrounded by a jelly layer composed of high molecular weight fucose-sulfate-rich glycoconjugates. At spawning, sea urchin sperm are exposed to the high pH of the seawater which leads to the activation of a Na^+/H^+ exchanger and a dynein ATPase causing an increase in motility. Factors released from the jelly layer, the sperm activating peptides (SAPs) further stimulate sperm motility and respiration. The majority of spermatozoa are unable to penetrate the jelly layer and remain immobilized at various depths within the jelly. Those that pass through must arrive in a physiological condition that both promotes binding and subsequently penetration of the vitelline membrane. Thus, in animals with external fertilization, sperm-oocyte ratios are extremely low and need to be enhanced by chemotactic mechanisms even to ensure a minimum of oocytes are fertilized. The outer jelly layer on the one hand attracts and traps spermatozoa, however incompetent spermatozoa (whether it be due to the sperm or the oocyte) are prevented from progressing towards the oocyte.

We have seen that also in mammals, few spermatozoa reach the oocyte under natural conditions, of those that do, some are not able to progress through the outer oocyte coating, the cumulus oophorus. A second extracellular coat, the zona pellucida, that impedes sperm progression even further is composed of several glycoproteins (ZP) that differ between species. The zona pellucida serves to modulate sperm binding and to protect the embryo during early development, however we know little about its topographical constitution and if indeed sperm entry is piloted to a specific site.

The most obvious morphological oocyte bottleneck is found in insects, squid and some teleosts. Here the oocytes lack cortical granules, the extracellular coat, the chorion, is impenetrable, and the spermatozoa lack an acrosome. In these species the spermatozoa enter the oocyte through a pre-formed entry site, the micropyle, where, in fish at least, a sperm attractant, a glyco-protein, has been identified responsible for guiding the spermatozoa to this area. In the anuran, *Discoglossus pictus*, oocytes are highly polarized with the animal pole marking the position of the meiotic plate and organelles distributed in a gradient towards the vegetal pole. Here the spermatozoa may only enter through a restricted depression at the animal pole, called the dimple, where the fine structural organization is different to the rest of the oocyte surface. In tunicates, the spermatozoon enters the oocyte at a preferential site at the vegetal pole. Polarized sperm entry coincides with polarized oocyte activation events. The first event being the release of calcium from intracellular stores which traverses the oocyte from the point of sperm entry to the antipode in a wave. For example, in jellyfish and the anuran *Xenopus laevis*, where the sperm enters the animal pole of the oocyte, the calcium wave starts at the animal pole

and traverses the oocyte to the antipode, while in ascidian and nemertean oocytes, the wave initiates at the vegetal pole, the site of sperm entry. In teleosts, where the spermatozoa are forced to enter at the animal pole through the micropyle, the calcium wave starts at the animal pole. In mammals and echinoderms the calcium wave is also initiated at the point of sperm entry however it is not known whether in these groups there are also preferential sperm entry sites. Finally, the last barrier for sperm interaction is the plasma membrane but to date there is still little information on its structure.

Sperm–Oocyte Encounters Are Infrequent in Nature

In the laboratory, we are used to seeing images of oocytes inundated with hoards of spermatozoa and this triggered the concept that fertilization was a haphazard “free for all,” analogous to a first order chemical reaction and that the first spermatozoon that successfully interacted with the egg triggered membrane mechanisms that blocked the entry of other spermatozoa. This is laboratory artifact. Activation events, triggered by the successful spermatozoon, occur at a rate independent of sperm concentration and serve to change the metabolism and morphology of the oocyte from a dormant cell to a dynamic zygote that needs to be protected from the environment throughout early development.

In nature sperm–oocyte ratios are very low. In some species they approach unity at source, while in others, that produce high numbers of sperm, massive loss by elimination, dilution and extracellular coat bottlenecks drastically reduce the final concentration at the site of fertilization. As spermatozoa progress through the extracellular layers, those encountering or responding to defective signaling fall by the wayside, until one, the successful spermatozoon, reaches its goal. It appears that selective pressures have favored the achievement of monospermy, rather than the prevention of polyspermy.

EMBRYOGENESIS

Cleavage and Cleavage Patterns in Embryogenesis

Heide Schatten, University of Missouri, Columbia, MO, United States

Introduction and Overview: Cell Division and Cleavages During Pre-Implantation Embryo Development

In early embryo development, a series of cell divisions take place that partition a large single cell, the fertilized oocyte, to become a complex multicellular organism, the mammalian embryo. The fertilized oocyte (zygote) surrounded by a thick external layer, the zona pellucida, is called conceptus. The zygote contains the genetic material from both male and female gametes which amounts to 23 chromosomes each. These combined 46 chromosomes undergo changes during a cell cycle before mitotic divisions occur resulting in the formation of the embryo with two and more cells. Early embryo development is distinguished by different stages which is based on the number of cells and the embryo's location in the female reproductive system, as shown in Fig. 1.

As research on human embryos is limited and largely restricted much of our knowledge on early embryo development and cleavage patterns comes from animal models such as the mouse, the pig, and the bovine systems. The mouse has been utilized for most developmental studies, as it is relatively easy to use for experimental purposes including the amenability for a wide variety of experimental manipulations but it is also different in some aspects from other mammalian systems that need to be taken into consideration when comparisons are made with human embryology. The porcine system has gained increased attention because of its use for biomedical purposes and as a model for human diseases. In this article data are presented that have been obtained from the mouse, the human, and also the pig.

In all mammalian (rodent and non-rodent) systems, after fertilization of the oocyte that takes place in the ampulla of either one of the two oviducts (Fallopian tubes) the fertilized oocyte (zygote) divides into two cells (two-cell stage) followed by five to six mitotic cell divisions. The individual cells resulting from these early cell divisions (cleavages) are called blastomeres. The zygotes of mammalian species undergo well-defined cell cycles but only very limited growth which results in smaller cells after each cleavage division while maintaining the same overall size as the zygote. A typical cell cycle in the early embryo takes between 10 and 12 h. At these early stages the term cleavage is primarily used to describe the division of cells through which the number of cells is increased without increasing the mass which is different from cell division cycles in somatic cells, as in early embryo cells cleavage divisions occur without increasing the volume of the conceptus. The individual blastomere cells resulting from cleavage divisions together

Fig. 1 Fertilization and pre-implantation development takes place at specific locations within the female reproductive system in approximately a time span of 1 week, as described in the text of this article.

form the compact early mammalian embryo, the morula. From the 8- to 16-cell stage flattening of the blastomere cells takes place, a process during which tight connections are formed between the individual blastomeres. This process is called compaction. The process of compaction is primarily mediated by the expression of E-cadherin, a Ca^{++} -dependent adhesion molecule which is essential for the compaction process. When E-cadherin is inhibited compaction does not take place. During the compaction stage from the 8- to 16-cell stage, deposition of extracellular matrix (ECM) occurs which also plays a role in signaling to the embryo cells.

Compaction results in two cellular lineages, the trophoblast which forms the fetal components of the placenta, the chorion, and the inner cell mass which will form the embryo proper. The trophoblast is important for the attachment of the embryo to the uterine lining (endometrium) before implantation can occur. The inner cells will form the inner cell mass (ICM) that will be re-organized into two layers: the epithelial epiblast that will form the embryo and amniotic membrane, and the hypoblast that plays a role in the orientation of the embryonic axes. Synchronous timing of pre-implantation embryo development and the mother's uterus is important for successful implantation, as embryo loss can occur if either one of these events is defective. Compaction of the pre-implantation embryo is a critical event, as fates of the individual blastomeres begin to change at this time to result in differences in individual blastomeres. The differences of individual blastomeres from each other are prompted by specific signals that are communicated to the different blastomeres. Specific signaling depends on several factors including the location of blastomeres within the pre-implantation embryo. These specific signals guide each blastomere's fate which now results in committed cells to pursue their developmental fates. Differentiation of cells includes their status from totipotency (the ability to undergo various cell fates) to pluripotency that allows development only into specific cells in the body. These pluripotent cells will then differentiate to commit to their fate throughout a lifespan.

At about 3 days after fertilization the 16-cell conceptus reaches the uterus. The conceptus continues to divide and in the uterus forms a ball of about 100 cells, called the blastocyst which starts to secrete fluid to form the blastocoel cavity. Blastocyst formation starts at the 16- to 32-cell stage, the morula stage. At this stage tight junctions are developed in the outer cells which do not allow fluid to pass. The outer cells now secrete fluid through a mechanism that involves action by a $\text{Na}^+ - \text{K}^+$ ATPase to pump sodium from the external environment into the embryo which is important for forming the blastocoel cavity. The accumulating fluid fills the blastocoel or blastocyst cavity. By the 64-cell stage (3.5 days) the embryo cells have differentiated and outer trophoblast (TE) cells and the inner cell mass (ICM) cells are clearly distinguished. At this stage the TE consists of about 45 cells while the ICM consists of about 15 cells. Until this time the embryo is still enveloped in the zona pellucida. Hatching from the zona pellucida occurs on day 5, a process during which the blastocyst is released from the zona pellucida and ready for implantation.

In this article, the early stages of development (pre-implantation stages) are discussed while other chapters in this Encyclopedia will detail the stages of implantation and post-implantation development resulting in the birth of a healthy offspring.

The stages of early embryo development are displayed in [Fig. 1](#) and summarized from the first cleavage stages to blastocyst formation as follows. Cleavage follows a partition pattern with no growth until the morula stage.

1-cell stage—fertilized oocyte (zygote)—*day 1*.

2-cell stage—developing embryo at ca 30 h (ca. 1.5 days) post insemination.

4-cell stage—developing embryo at ca 40 h post insemination (ca. 2 days).

8-cell stage—developing embryo at ca 2.5 days post insemination.

16-cell stage—morula; developing embryo at ca 3 days post insemination.

32-cell stage—*morula*, divisions and differentiation takes place in equal-sized blastomere cells of the developing embryo at ca 3 days post insemination.

58-cell stage—early blastocyst developing embryo at ca 4 days post insemination.

107-cell stage—late blastocyst developing embryo at ca 4.5 days post insemination.

The early blastocyst at ca 4.5 days post insemination displays formation of ICM, trophoblast, blastocoel. During blastulation hundreds of cells are produced resulting in the trophoblast that gives rise to the chorion and placenta; the ICM gives rise to the organism, the embryo, while the blastocoel provides nutrients ([Figs. 2 and 3](#)).

Fig. 2 From the 8-cell stage (left) to the blastocyst stages (right) numerous cleavages take place resulting in a well-defined blastocyst with TE and ICM cells.

Fig. 3 Shown here are cell divisions during compaction from the 8- to 16-cell stages (8/16) when outer cells (TE cells) and inner cells (ICM cells) are established. *BI*, blastocyst; *TE*, trophectoderm; *ICM*, inner cell mass. Modified from Vinot S, Le T, Ohno S, Pawson T, Maro B, Sophie Louvet-Vallée S (2005). Asymmetric distribution of PAR proteins in the mouse embryo begins at the 8-cell stage during compaction. *Developmental Biology*. 282, 307–319.

Section 2: The Process of Cell Divisions and Establishment of Symmetric and Asymmetric Cleavage Division Patterns

The mechanisms of cleavage divisions are overall similar to cell divisions in other cells in which two major cytoskeletal elements play a role, which are microtubules and microfilaments. Microtubules form the mitotic apparatus (mitotic spindle) whose main function is to separate chromosomes to the newly dividing cells (Fig. 5). These microtubules are organized from centrosomes (microtubule organizing centers; MTOCs) at the two opposite mitotic poles. Two classes of microtubules exist in the mitotic spindle that are important for spindle functions and either connect the two poles (polar microtubules) or connect the polar centrosome from one half of the spindle to the kinetochores of chromosomes of the same half (kinetochore microtubules) (Fig. 5). The mechanisms for embryonic cleavage divisions differ to some extent in rodent and non-rodent mammalian embryo systems. In blastomeres of non-rodent early mammalian embryos centrosomes contain centrioles (microtubule-based tubular structures; see Fig. 5) that are brought into the non-rodent oocyte by sperm at fertilization while blastomeres of rodent early mammalian embryos do not contain centrioles; the sperm in rodent species does not contribute a centriole to the fertilized oocyte. It has been shown that centrioles are not even tolerated by the early rodent embryo and are destroyed if experimentally introduced into the rodent oocyte. In contrast to non-rodent mammalian species rodents display different mechanisms for meiotic and mitotic spindle formation (reviewed in Schatten and Sun, 2011a,b, 2017) up to the early blastocyst stages when centrioles are formed de novo in rodents to participate in subsequent cell divisions. *Microfilaments* located underneath the cell surface play a major role during blastomere cell shape changes and during cytokinesis at the end of cell division when a contractile ring forms between cells to separate the dividing blastomere cells.

In the mouse, the first cleavage occurs at about 16–20 h after fertilization, and the following cleavages each take roughly 12 h. The cell cycle length varies not only among different embryos but even among blastomeres within the same embryo.

The first cell divisions (cleavages) in the mammalian embryo are symmetric while later cell divisions are asymmetric, resulting in distinctly different cells after cytokinesis is completed (Fig. 5 right panel). Unequal cleavages in the mammalian embryo typically occur after asymmetric positioning of the mitotic spindle (Fig. 5, right panel from Marikawa and Alarcón, 2009).

The specific cleavage patterns of embryo cells are only known to some extent. In general, cleavage patterns of blastomeres of 8-cell stage embryos and of external blastomeres of 16-cell stage embryos can be categorized into two groups: symmetric and asymmetric. Symmetric cleavage is defined as the plane of cell division being parallel to the apical–basal axis which results in two external blastomeres; asymmetric cleavage is defined as the plane of cell division being perpendicular to the apical–basal axis, resulting in one external and one internal blastomere (Fig. 5, right panel).

An apical–basal polarity occurs in all eight blastomeres. The number of external and internal blastomeres at the 16-cell stage varies among embryos and amounts to an average of 6–7 internal and 9–10 external blastomeres. The fifth cleavages generate more external and internal cells, and 12–13 internal and 19–20 external blastomeres are present at the 32-cell stage embryo.

The mechanisms and timing of regulation for compaction is not yet completely understood but based on the available data it is likely not controlled by the number of cell divisions, as the inhibition of blastomere division or DNA replication does not delay the process of compaction.

To gather conclusive data studies of fourth cleavages in developing embryos using time-lapse video approaches have revealed that the planes of cell divisions can occur in various different positions relative to the apical–basal axis. It suggests that the orientations of cleavage planes can vary and are strictly following a parallel or perpendicular orientation to the apical–basal axis. Such flexibility in patterning is also observed during the fourth and fifth cleavages. As is known for mitotic cells, a mitotic blastomere cell first becomes spherical and divides into two round blastomeres, which then flatten and incorporate smoothly into the whole embryo. These studies have shown that TE and ICM cells are not strictly determined by cleavage orientations and can alter between symmetric and asymmetric patterns at the fourth and fifth cleavages. At this time it is not clear whether cleavage orientations are regulated by molecular factors such as fate determinants, for example *Cdx2*, that have been studied extensively in the mouse system. Different technologies such as targeted knockout/knockdown of specific gene products combined with high-resolution live cell imaging will be needed to analyze in more detail the timing and requirements for accurate cell divisions leading to implantation-compatible pre-implantation embryos.

As mentioned above, because research on humans is limited and to a large extent restricted much research has been performed on animal models such as the mouse, porcine and bovine systems to understand the mechanisms involved in early cleavages and embryo development. However, animal systems are different in various aspects, including the occurrence of mitotic aneuploidies (chromosomal imbalances; imbalances in chromosome numbers) that are more frequent in the human and are major causes for implantation failures and embryo loss. Studies in animal models have allowed experimental manipulations in order to obtain more informed data for cleavage divisions and embryo development. Much of the experimental research for the past decades has been performed in the mouse. For example, cell fate determination of individual cells has been extensively studied in the mouse, as the mouse system is highly amenable to experimental manipulations. In the mouse embryo and perhaps all other mammalian species, successive asymmetries develop during embryo development. While the issue is not yet completely resolved experimental studies including micromanipulation techniques, blastomere isolation, aggregation, and transplantation, have resulted in concluding that the fates of blastomeres are not determined until the fifth cleavages. During the last decade more data have become available to show that individually dissociated blastomeres of 16- or 32-cell stage embryos become re-aggregated as a single mass with both types of aggregates being capable of forming expanded blastocysts with the correct associations and expressions. These experiments have shown that the location of blastomeres (i.e., external or internal) at around the 32-cell stage is tightly linked to the commitment towards TE or ICM lineage.

While the mouse has allowed us to gain fundamental knowledge and critical data for mammalian embryo development the porcine and bovine systems are being explored increasingly, as these systems in several aspects are important for biomedical research applications for humans and because several cell and molecular processes are similar to those in human reproduction. For example, in humans but not as frequently in other mammalian reproductive systems, meiotic and mitotic error rates are high compared with other mammalian species. Mitotic and cleavage errors resulting in abnormalities are manifested in aneuploidies which are a major cause of implantation failure and embryo loss (Niakan et al., 2012). It has been reported that aneuploidies may occur in one or more blastomeres in more than 80% of human pre-implantation embryos in which abnormal cleavage divisions have been observed. Time-lapse imaging of live human embryos (Wong et al., 2010; Fig. 4) revealed that timing of the early cleavage divisions is especially important for proper embryo development and implantation to avoid embryo loss (reviewed in Niakan et al., 2012). This knowledge is particularly important for in vitro fertilization (IVF) and other assisted reproductive technologies (ARTs) in which adequate in vitro culture of embryos is an important criterion for achieving successful pregnancies and birth of a healthy baby.

In vitro fertilization (IVF) is increasingly being performed to help infertile couples to conceive a child. In this procedure oocytes are removed from the ovary and fertilized with sperm outside the female reproductive tract. The fertilized egg or early embryo is then

Fig. 4 Time-lapse imaging of live human embryos shows cleavage divisions up to the blastocyst stages.

Fig. 5 Mitotic apparatus of first embryonic cell division in rodent (left) and non-rodent (center) species. Rodent systems are different from non-rodents in that a centriole is absent from the center of the centrosome complex while it is present in non-rodent species (for review see Schatten and Sun, 2011a,b, 2017). During early cleavage divisions symmetric and asymmetric cleavages can take place (right).

returned to the woman's uterus where embryo development will take place as known for in vivo-fertilized eggs. This procedure is frequently applied for various reasons, for example when fallopian tubes are damaged or blocked, when hormonal imbalance is experienced or when the woman has endometriosis.

IVF has been used successfully since 1978, when the first child conceived by this procedure was born. Since then thousands of couples have chosen IVF or other ART technologies and methods for improving ART have been developed, recognizing the importance of timing for cleavage as mentioned above.

Embryo selection is among the critical aspects of predicting successful embryo development, implantation, pregnancy, and birth of a healthy baby when IVF is performed.

As aneuploidy is among the highly probable causes for implantation failure, for IVF, time-lapse monitoring primarily uses grading of cleavage-stage embryos to assess the degree of embryo fragmentation, number of nuclei and size, and number and symmetry of blastomeres in the embryo. In humans, high-quality cleavage-stage embryos (day 2 and 3) display four cells on day 2 and eight cells on day 3. On day four, a high-quality morula has developed, with the fourth round of cleavage divisions and compaction. On day 5, the high-quality blastocyst is fully expanded and ICM and TE cells can easily be distinguished. Mitotic aneuploidies, while observed in all developmental stages, are more common during the first three mitotic divisions.

Mitotic aneuploidies may not only contribute to implantation failure but to fetal complications if implantation has taken place, such as intrauterine growth delay, congenital malformations, mental retardation, and uniparental disomy.

Future research using new technologies and methodologies such as single-cell analysis is expected to provide new information on lineage segregation and molecular mechanisms underlying cell and developmental key events. In addition, microscopy and new imaging modalities will contribute valuable data on live and fixed cell samples to enhance our knowledge of cell and molecular events underlying embryo development.

Glossary

Chromatin The filamentous material that makes up the eukaryotic chromosome consisting of DNA, histones, and other packaging proteins.

Cytokinesis The physical separation of two daughter cells following mitosis or meiosis.

Haploid Having a single set of chromosomes. Note: Most animals have *diploid* somatic cells (with two paired sets of chromosomes), but produce haploid gametes.

Intron A portion of a gene that is transcribed into RNA but is removed before the remaining *exons* are translated into protein.

Mitosis Part of the cell cycle in which replicated chromosomes are separated to form two new nuclei.

Nucleosome The basic structural unit of chromatin, consisting of a DNA duplex wound around a core of eight histone proteins.

Pioneer factor A specialized transcription factor that establishes or maintains open chromatin at its binding sites; the first factor to engage a region of repressive chromatin.

Pluripotent Capable of giving rise to many of the cell types that make up the body of an organism. Note: As cells undergo *differentiation*, they become restricted in which cell types they can produce.

Transcription The first step of gene expression in which the genetic information encoded in DNA is transferred to RNA.

Introduction: Life Starts Under Maternal Control

In nearly all animals, the embryo relies exclusively on maternal gene products during the first hours following fertilization. At this time, the newly formed zygotic genome remains transcriptionally silent (Newport and Kirschner, 1982b). All the proteins and RNAs needed for this phase of development are produced in the mother and packaged into the egg (Tadros and Lipshitz, 2009). Ultimately, control of development is passed to the zygotic genome through a hand-off known as the maternal-to-zygotic transition (MZT). The MZT encompasses two coordinated processes: the clearance of maternally supplied products and zygotic genome activation (ZGA) (Tadros and Lipshitz, 2009).

Activation of the zygotic genome is ultimately required for survival as maternal products are only capable of driving development for a limited time. To become an adult, an organism must produce an array of diverse cell types and this, in turn, requires the precise expression of select genes. Gene expression is rapidly adjusted to accommodate developmental transitions and to respond to changes in the environment. Thus, as development continues, the prepackaged supply of maternal products must be replaced by proteins and RNAs produced from the zygotic genome to allow the embryo to be responsive to these signals.

In this article, we provide a brief description of the processes that shape the activation of the zygotic genome. In “**Part I: Silence Buys Time**” we discuss the developmental requirements for a period of transcriptional quiescence, and in “**Part 2: Orchestrating the Transfer of Power**” we discuss the mechanisms that enable genome activation.

Part I: Silence Buys Time

The newly assembled zygotic genome must be reprogrammed to allow for embryonic development. The period of transcriptional silence that follows fertilization enables this reprogramming to be carried out. This delay ensures that developmental genes are prepared for expression and provides time for the repeated duplication of the genome, allowing the embryo to increase its production capacity.

Time for Reprogramming

At fertilization, the egg and sperm each contribute one haploid set of chromosomes, which combine to form the new zygotic genome. These chromosomes have been repurposed; they come from two highly specialized cells in which they served to produce a specific set of gene products. To be of use to the embryo, the genome needs to be reprogrammed: the gamete-specific expression program must be erased and the genes needed for early development must be prepared for expression.

Much of our understanding of genome reprogramming stems from efforts to manipulate cell identity. Roughly half a century ago, John Gurdon generated living tadpoles from the nucleus of a fully-differentiated, adult frog cell using a technique now known

as somatic cell nuclear transfer (Gurdon, 1962). In this method, a somatic nucleus is transplanted into an enucleated egg. Cytoplasmic components of the egg reprogram the transplanted genome to allow it to give rise to a new organism. Thus, Gurdon's achievement revealed that all the factors required to revert the somatic nucleus to a pluripotent state come packaged within the egg.

Building on this work, in 2006, Takahashi and Yamanaka generated the first induced pluripotent stem cells (iPSCs). By forcing differentiated cells to express a defined set of transcription factors they converted them to a pluripotent state, much like that of an embryonic stem cell (Takahashi et al., 2006). Since this seminal discovery, many attempts have been made to improve the efficiency of this process in hopes of developing new treatments for disease. Importantly, this work has highlighted the central role that transcription factors and chromatin regulation play in reshaping cell identity.

The reprogramming that takes place in the embryo during the MZT mirrors this in vitro reprogramming. In both cases, the previous cell identity must be cleared to return the genome to a pluripotent state. This flexible chromatin state is what allows iPSCs to be differentiated into numerous cell types and makes them a promising therapeutic tool. Likewise, pluripotency grants the embryo the capacity to give rise to all the diverse cells that make up the adult.

Time for Amplification

The MZT is a highly conserved process. It occurs in nearly all animals and even in some plants. Nonetheless, much of what we know about this transition has been gleaned from a few model species including the fruit fly (*Drosophila melanogaster*), zebrafish (*Danio rerio*), frog (*Xenopus laevis*), and mouse (*Mus musculus*) (Tadros and Lipshitz, 2009). While many features of the MZT are shared across species, the timing of this transition differs substantially, both in terms of hours post-fertilization and in terms of cell cycle number (Fig. 1).

Many animals, including frogs and zebrafish, undergo a series of rapid, synchronized cellular divisions after fertilization. These divisions generate a ball of cells, called a blastula, which occupies the same volume as the egg (Tadros and Lipshitz, 2009). Flies undergo a similar process but without cytokinesis. Their nuclei are replicated in a common cytoplasm until the end of the MZT, at which time they are engulfed by cell membranes to form individual cells (Tadros and Lipshitz, 2009).

The mammalian MZT follows a different paradigm. In mice, the first cell cycle takes about a day. For comparison, the first replication cycle takes a mere nine minutes in flies. In the three hours it takes the fly embryo to complete 13 nuclear divisions and undergo ZGA, the mouse embryo is only an eighth of the way through its first cell division (Tadros and Lipshitz, 2009). These different developmental strategies can be traced to the environment of the developing embryo (Yuan et al., 2016). In the protected environment of the mammalian uterus, an embryo has plenty of time to carefully execute a day-long cell cycle. Whereas, if an externally developing embryo is to survive after being abandoned in a hostile environment, it must develop quickly.

Though it may be slow to replicate, the mammalian genome requires little amplification prior to activation. While the fly genome undergoes 13 pre-ZGA replications, the mouse genome is ready after only one (Tadros and Lipshitz, 2009). Again, this difference stems from the unique environments of the developing zygote. Unlike the tiny, placenta-fed mammalian embryo, an externally developing embryo must be loaded with all the nutrients the animal will need prior to hatching (Yuan et al., 2016). A huge cell is required to accommodate this supply. Yet, like any cell, the embryo begins life with only a single genome. Within its bulky cytoplasm, the transcriptional output of one genome is not enough to produce the rapid changes in protein and RNA levels required for development. Thus, in egg-laying species, extensive amplification is needed for the genome to reach sufficient production power.

Part 2: Orchestrating the Transfer of Power

The MZT is not accomplished through a sudden coup but through a gradual relinquishing of maternal control. Accordingly, ZGA is also a progressive process. While embryos experience a major burst of transcription near the end of the MZT, a small subset of genes is expressed much earlier (Harrison and Eisen, 2015). The products of these early genes help prepare the embryo for ZGA by clearing maternal products, modifying the chromatin, and serving as transcriptional activators (Lee et al., 2014). Thus, gene activation is precisely regulated such that each gene is turned on at a particular time.

While the exact sequence of molecular events that leads to ZGA remains unclear, several mechanisms that regulate its onset have been elucidated. To initiate transcription, a permissive chromatin environment is established, transcriptional activators outcompete maternal repressors, and the cell cycle slows.

Prime the Chromatin

In eukaryotes, the expansive genome is compressed to fit it inside the nucleus. DNA is wrapped around histone octamers to form nucleosomes, and linker histones bundle nucleosomes together to provide further compaction. Often, this packaging creates a physical barrier that prevents the transcriptional machinery from accessing the DNA, silencing the expression of underlying genes. In this way, chromatin packing is an important regulator of gene expression.

The cell uses several mechanisms to adjust chromatin accessibility. Nucleosomes are shifted along the DNA or ejected by remodeling complexes. Within the nucleosome, histone variants are swapped in for the standard set and chemical modifications are added to histone tails. These changes can alter how tightly a nucleosome interacts with DNA or serve as a signal that blocks or promotes the

Fig. 1 Zygotic genome activation is shared amongst animals, but the timing of activation differs. Early embryonic development is summarized for four model species, indicated on the right. The “1 cell” stage, an intermediate stage, and the stage at which major onset of ZGA occurs are illustrated. The later stages are labeled with the cleavage cycle number, and the absolute time of ZGA (in hours post fertilization) is included in parenthesis. The timing of clearance of maternal products and activation of zygotic transcription are represented by curves below, and the period of pluripotency is marked with a bar.

recruitment of chromatin regulators. During the first hours of development, a variety of such mechanisms are used to shape the chromatin, ensuring that only the right genomic regions are accessible for activation.

Given the abundance of histones in the early embryo, one might imagine that the DNA would be saturated, contributing to global transcriptional repression. Yet, across species, early chromatin appears to be relatively open (Pálffy et al., 2017). Growing evidence suggests that this chromatin exists in a “naïve” state, analogous to a blank slate. Notably, early chromatin is devoid of histone modifications that typically accompany gene expression (Harrison and Eisen, 2015).

During the MZT, reprogramming erases the gamete cell identity and produces a permissive state that serves as the starting point for genome activation. Right before the major onset of transcription, the genome’s three-dimensional organization becomes more defined (Flyamer et al., 2017; Hug et al., 2017). At the same time, embryonic histone variants are replaced by somatic versions, histone modifications become prevalent, and nucleosomes are repositioned near critical genes (Harrison and Eisen, 2015; Pálffy et al., 2017; Fig. 2A). Together, these changes make the chromatin transcriptionally competent and give activators access to the correct genomic sites.

Overcome Maternal Repression

In the 1980’s Newport and Kirschner proposed that the cell cycles of the early embryo served as a developmental timer (Newport and Kirschner, 1982a,b). As the genome is duplicated within the unchanging cytoplasmic volume of the embryo, the exponentially increasing DNA could titrate a maternally supplied repressor. According to this model, once the DNA levels reach a certain threshold

Fig. 2 Multiple complementary mechanisms regulate the onset of zygotic transcription. (A) After fertilization, the chromosomes are reprogrammed to a more naïve state. As the genome is activated, the chromatin is reorganized into defined regions, nucleosomes are repositioned, and histones are post-translationally modified at specific sites. (B) A maternally supplied repressor blocks transcription in the early embryo. As the genome undergoes replication, the exponentially increasing DNA titrates away this repressor, allowing transcription to initiate. Evidence suggests that histones may function as such a repressor. (C) A key transcriptional activator is limiting in the early embryo. Accumulation of this activator enables transcription of target genes. (D) The rapid, early cell cycles interrupt transcription. Cell cycle slowing allows time for completion of transcription.

there is no longer a sufficient quantity of the maternal repressor to silence the genome, allowing for transcriptional activation (Fig. 2B). In support of this model, altering the DNA content of the embryo shifted the timing of ZGA in a number of species (Pálffy et al., 2017).

Naturally, this model hinges on the existence of a titratable repressor. For years, efforts to identify this hypothetical repressor were largely unsuccessful. The few candidates that were identified could only account for the repression of a handful of genes (Tadros and Lipshitz, 2009). However, recent data supports a model in which histones serve a global repressor function (Pálffy et al., 2017). Notably, manipulating histone levels in zebrafish embryos affects the timing of ZGA (Joseph et al., 2017). Histones are maternally deposited in great excess but are progressively titrated by the exponentially increasing DNA content. Fittingly, in zebrafish, a drop in the nuclear histone concentration coincides with the ZGA (Joseph et al., 2017). Histones seem intuitively well suited for global repression; they bind ubiquitously across the genome and prevent gene expression by blocking the access of the transcriptional machinery. However, the density of histones on DNA changes very little in the developmental stages leading up to ZGA. Instead, it is the excess of non-DNA-bound histones that appears to serve as a ZGA timer. In this model, the unbound histones compete with transcriptional activators for binding to DNA. As relative histone levels decrease, activators are able to

successfully compete for DNA binding, and the balance is shifted toward transcriptional activation. Thus, excess histones may serve as a buffer against premature transcription while the genome is reprogrammed.

Accumulate Activators

In theory, the accumulation of a transcriptional activator could also serve as a ZGA timer (Fig. 2C). The classic example of a rate-limiting activator is TATA binding protein (TBP). TBP is a general transcription factor that helps position the transcriptional apparatus over the start of a gene. In the early frog embryo, TBP is present as mRNA, but it is not translated at detectable levels until right before ZGA. The timely increase in the levels of this protein coincides with widespread activation of transcription (Lee et al., 2014).

In addition to general factors, gene-specific transcription factors are also required to ensure that only the correct genes are activated during ZGA. These factors bind to specific DNA sequences, and thus, help to direct the transcriptional machinery to the correct locations. A handful of global genome-activating transcription factors have been identified (Zelda in flies (Harrison and Eisen, 2015), Pou5f3 in zebrafish (Onichtchouk and Driever, 2016), and DUX/DUX4 in mammals (Iturbide and Torres-Padilla, 2017)). These genome activators share a number of features. They bind early in development and promote the activation of hundreds of genes during the major onset of transcription. Their binding is required for the expression of the earliest zygotic genes, and notably, they all appear to function as “pioneer factors.” Pioneer factors are a specialized class of transcription factors that are characterized by their ability to bind to regions of repressive chromatin. Following binding, these factors promote chromatin accessibility, allowing other factors to access the local DNA (Zaret and Carroll, 2011).

Still, the mechanism by which these early transcriptional activators reprogram the genome remains unclear. These factors are maternally deposited and massively upregulated in the hours leading up to ZGA. Thus, they have access to the genome while the chromatin environment is being remodeled and may exploit this nascent state to access their binding sites. Furthermore, recent work in zebrafish suggests that genome activators may use “strength in numbers” to take on the nucleosome (Joseph et al., 2017). As histone levels decrease, the rising levels of transcriptional activators may allow them to outcompete histones for access to DNA. By occupying their binding sites, these activators could shape local nucleosome positioning to favor gene expression.

Allow Time for Transcription

In many species, the early cell cycles occur with unrivaled speed (Tadros and Lipshitz, 2009). Because nascent transcripts are aborted as the chromosomes condense during mitosis, these short cycles leave only a brief window of time for transcription. This constraint is reflected by the fact that early expressed genes tend to be short and lack introns (Lee et al., 2014).

Initially, the embryo undergoes a stripped-down version of the cell cycle. The cell switches between replicating its genome and mitotically dividing, skipping the G1 and G2 gap phases entirely. But over the course of the MZT, the cell cycle slows and a G2 is introduced at the end of this transition (Tadros and Lipshitz, 2009). Thus, it was proposed that cell cycle slowing gradually permits gene expression, culminating in a major burst during the first G2 pause (Fig. 2D).

This model is supported by data from frog embryos, in which experimentally arresting the cell cycle resulted in premature transcription (Lee et al., 2014). But, at least in flies, the relationship between transcription and the cell cycle is likely bidirectional. While arresting the cell cycle can allow for precocious transcription, zygotic transcription is also required to produce proteins that slow the cycle. Transcription may also generate DNA replication stress that contributes to the slowing (Blythe and Wieschaus, 2017). Regardless, the abbreviated replication cycles of the early embryo place limits on transcription that are released as the cycle slows (Yuan et al., 2016).

Conclusion: A Peaceful Handoff Requires Coordination

For development to occur, the genome must produce the correct products, in the right amounts, at specific times. To be prepared to perform this essential function, the genome remains transcriptionally silent during the first stages of development while it undergoes remodeling and rapid replication. The egg is loaded with all the factors necessary for the initial steps of embryogenesis to allow development to proceed during this reprogramming. These maternal products allow the animal to rapidly progress through this vulnerable stage of life. Thus, the MZT has evolved to accommodate the specific needs of the fertilized egg. It allows a giant cell to amplify its inchoate genome without a costly delay in development.

To move the embryo from maternal to zygotic control, the transcriptome is overhauled; maternal transcripts are progressively degraded while the zygotic genome becomes transcriptionally active. These changes occur with precise dynamics such that each transcript is present in the correct amount throughout this transition. The embryo uses a diverse set of mechanisms to execute this complicated handoff. These complementary mechanisms feed back on themselves to reinforce the shift toward zygotic control. As the exponentially increasing DNA overwhelms the supply of maternal repressors and the cell cycle slows, the first zygotic genes are expressed. Some of these early expressed zygotic factors promote the degradation of maternal products, reinforcing the maternal decline and allowing for further zygotic transcription.

Simultaneously, the chromatin of the fertilized egg is reprogrammed to enable the generation of an entirely new organism. This dramatic reorganization of the embryonic genome is similar to the *in vitro* reprogramming attained through either somatic cell

nuclear transfer or the induction of specific transcription factors. In some cases, the same factors function across these contexts. Understanding reprogramming in the context of the developing embryo, where it is accomplished with unprecedented efficiency, will offer important insights not only into a shared and essential aspect of animal development, but may also suggest strategies to increase reprogramming efficiency in culture.

Glossary

Blastocyst A mammalian embryo at the final stage of development that is competent to implant in the uterus.

Morphologically, it appears as a hollow sphere consisting of two tissue types or cell lineages, the trophectoderm and inner cell mass. The trophectoderm is responsible for implantation and placentation, whereas the inner cell mass gives rise to the fetal body and the extraembryonic tissues, amniotic sac and yolk sac.

Cavitation The process that forms a fluid-filled space in the blastocyst. It is mediated by the trophectoderm, which regulates the directional transport of fluid from the external environment into the developing blastocyst.

Conceptus The products of the fertilized egg, namely the embryonic and extra-embryonic tissues, which form the fetal body and tissues that do not become part of the body (e.g., placenta, amniotic sac), respectively. It is distinct from the term “embryo,” which refers to tissue that forms the body. The blastocyst can also be called a conceptus.

Epithelium A type of tissue which covers or lines the surface of tissues or organs. It functions as a selective barrier, regulating the movement of molecules between the internal and external environments of a tissue or organ. Epithelial cells are characterized as having apical-basal polarity, and are attached to each other by complexes of proteins, including the tight junctions. A simple epithelium, such as the trophectoderm, consists of a single layer of flat-appearing cells owing to being stretched by the expanding blastocyst cavity.

Preimplantation The period of development between the fertilization of the egg and implantation in the uterus. It occurs in the oviduct (fallopian tube) and ends when the conceptus arrives in the uterus.

Introduction

The trophectoderm (TE; from the Greek “trophe,” “ektos” and “derma,” meaning to feed, outside and skin, respectively) is a simple epithelium that makes up the outer wall of the blastocyst (from the Greek “blastos” and “kystis,” meaning bud or sprout and bladder) (Fig. 1A). It is the first tissue to differentiate during preimplantation development, and it is unique to a distinct group

Fig. 1 Preimplantation development. (A) Schematic representations from fertilization to blastocyst formation. Trophectoderm (TE) differentiates as the outer layer that surrounds the inner cell mass (ICM) and blastocyst cavity. A photograph of a mouse blastocyst at around 3 days after fertilization is shown on the right. (B) A photograph of a blastocyst that is hatching out of the zona pellucida is shown. (C) Immunofluorescent visualization of the cell type-specific transcription factors (CDX2 for TE and OCT4 for ICM) in a blastocyst at around 4 days after fertilization. Scale bars = 50 μm.

of mammals called the eutherians, also known as the placental mammals (Eakin and Behringer, 2004). Some examples are human, mouse, dog, and cattle. The hallmark feature of TE is its adaptation for invasion and implantation in the uterus, after which it contributes to the formation of the placenta. The viviparous mode of reproduction of eutherians is made possible by the placenta, which functions in the nutritive and respiratory exchanges between mother and fetus. However, prior to implantation, the TE plays a different role. It transports fluid from the environment into the blastocyst, causing it to increase in diameter. Since the blastocyst is encased by a glycoprotein layer called the zona pellucida, it must hatch from its confinement before the TE can interact with the uterus. It has been observed that when human and mouse blastocysts are cultured outside the maternal body in a Petri dish in a laboratory setting, their expansion due to fluid accumulation appears to promote the tearing of the zona pellucida (Fig. 1B). The failure of hatching leads to the inability of the blastocyst to implant and the failure to produce pregnancy.

In this article, we will examine TE development based on studies conducted primarily in the mouse. It is a popular experimental system because it is amenable to investigations of mechanisms at the cellular and molecular level and is a useful proxy for human since the two species undergo similar morphological changes during the preimplantation period. We will first provide a morphological overview of the emergence of the TE epithelium in the developing blastocyst. We will then discuss the HIPPO signaling pathway and its regulation by cell polarity as the molecular basis of how cells are segregated to differentiate into the TE cell type. Lastly, the current knowledge of TE development is applied to examples of clinical issues that are significant to human reproduction and fertility.

Morphogenesis of the Trophectoderm Epithelium

Preimplantation development prepares the conceptus for attachment to the endometrium, the inner lining of the uterus. The process takes place in the oviduct (fallopian tube), and it begins with the egg. At approximately 60 μm in diameter, the egg is so tiny that it can only be seen with the aid of a microscope. Yet it is one of the biggest cells in the adult body. The sperm must penetrate the zona pellucida to fertilize the egg and produce the conceptus (Fig. 1A). Consisting of only one cell at the start, the conceptus cleaves or divides to increase cell number without growth, so that daughter cells are eventually reduced to the size of adult cells. At approximately 2 days after fertilization, the conceptus appears as a ball of cells or morula (from the Latin “morus,” meaning mulberry), consisting of eight cells. It is from this stage onward that the TE epithelium is gradually constructed. The morula has a bumpy surface that alters dramatically during the process of compaction. Cells change from spherical to wedge shape owing to increases in adhesion between neighboring cells, causing the bumpy surface to smoothen (Fig. 2). This marks the establishment for the first time of the apical-basal polarity in cells. It is the specialization of the plasma membrane into distinct domains that face the external environment (apical) and neighboring (basal) cells. By the 16-cell stage, the morula arranges into an outside layer of cells surrounding a central cluster of cells (Fig. 3). The spatially segregated cells are the progenitors of the first two tissue types in the blastocyst, the TE and inner cell mass (ICM), the latter of which will give rise to the fetal body. The outside cells retain polarity (Fig. 3) and assemble intercellular complexes of tight junction proteins between the apical and basal domains, creating a boundary that segregates the specific functions of the two domains. At 3 days after fertilization or approximately 32-cell stage, a fluid-filled

Fig. 3 Establishment of apical-basal cell polarity. Outside and inside cells are generated by the 16-cell stage, as progenitors of TE and ICM, respectively. Distinct apical and basal membrane domains are retained in outside cells.

Fig. 4 Formation of the blastocyst cavity. (A) A series of snapshot images that span the period of 3 h around the 16- to 32-cell stages, highlighting the emergence and expansion of the blastocyst cavity. An *arrow* points to a microlumen. (B) Schematic representations, depicting a sequence of cellular and molecular events that lead to cavity formation. (C) Immunofluorescent visualization of Z01 protein (*green*), a key component of tight junction, in the blastocyst. Nuclei (*blue*) are also stained. Scale bars = 50 μ m.

cavity forms inside the morula, transforming it into the blastocyst. The outside cells have matured into the TE epithelium, functioning as a selective barrier between the internal milieu of the blastocyst and the external environment. The blastocyst appears as a hollow, ovoid structure, consisting of a single layer of flat TE cells surrounding the aggregate of ICM cells in one side and the fluid-filled cavity in the other side (Fig. 1A). TE cells adjacent to the ICM and adjacent to the cavity are designated as the polar TE and mural TE, respectively. At 4 days after fertilization, the expanding blastocyst arrives in the uterus, hatches, and is ready for implantation. A time-lapse movie of mouse development, showing progression from the 2-cell stage to the blastocyst stage (Kono et al., 2014), can be viewed online in the PubMed database (<https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4404313>, see under Supplementary Material, Movie 1: control): images of the conceptuses were captured every 15 minutes over a period of 3 days of culture in a Petri dish.

The blastocyst cavity is essential for hatching and for promoting interactions between the TE epithelium and the endometrium by increasing the surface area of the conceptus. The key to generating the cavity is the TE cell polarity that enables directional transport of fluid, and it involves several steps (Fig. 4A and B). First, the basal domain serves as the target site for the exocytosis of membrane vesicles that generate microlumens (small spaces) between the outside cells. Second, distinct ion pumps are differentially distributed in the apical and basal domains that enable the directional transport of sodium ions from the external environment into the microlumens. As sodium ions accumulate, osmotic pressure elevates, drawing in water and expanding the microlumens, which coalesce to create a single fluid-filled cavity. Finally, to retain fluid in the cavity, an impermeable seal is created by the tight junctions between the TE cells (Fig. 4B and C). The seal also enables blastocyst expansion during hatching, and the increase in surface area enhances contact with the endometrium. Establishment of the apical-basal cell polarity is essential for proper morphogenesis of TE, as the experimental disturbance of cell polarity in the mouse conceptus causes the abnormal distribution of tight junction components and the absence of an impermeable seal (Alarcon, 2010). Consequently, blastocyst cavity formation fails, and the conceptus appears as a morula.

Molecular Mechanisms of Trophectoderm Development

Both the TE and ICM have identical genetic composition, since they originate from the same fertilized egg. However, which genes are transcriptionally activated or repressed are profoundly different between them. Genes that are specifically activated in the TE are responsible for various functions unique to TE, such as blastocyst cavity formation, implantation, and trophoblast development. In contrast, ICM expresses genes that are involved in the maintenance of pluripotency, i.e., the developmental capability that generates various tissues to make the fetal body. Hundreds of genes are specifically expressed in the TE by the time the blastocyst cavity is expanded. Some of the TE-specific genes start their expression at the 16- to 32-cell stages before cavitation occurs, and they play critical roles in the development of functional TE. An example is *Cdx2* gene, which encodes a transcription factor, i.e., DNA-binding protein that activates or represses transcriptions of other genes (Fig. 1C). When the fertilized egg is experimentally created from sperm and oocyte that completely lack the *Cdx2* gene, the resulting morula initially forms the blastocyst cavity but fails to maintain it due to impaired epithelial tight junctions (Strumpf et al., 2005). Moreover, the *Cdx2*-deficient conceptus has reduced expressions of other TE-specific genes (e.g., *Eomes*) and also abnormal ectopic expressions of ICM-specific genes (e.g., *Oct4* and *Nanog*) in the outside cells. *Cdx2* is one of the key regulators of TE development that coordinate differential gene expressions, specifically by up-regulating transcription of other TE genes while repressing transcription of ICM genes.

One of the fundamental questions in elucidating the mechanisms of TE formation is how differential gene expressions between the TE and ICM are achieved. Although the details of such mechanisms are still under investigations, a critical role is played by HIPPO signaling (Cockburn et al., 2013; Hirate et al., 2013). HIPPO signaling is an intracellular signal transduction machinery, consisting of over a dozen of interacting protein components, which regulate transcription of genes that control proliferation and differentiation in various cell types (Fig. 5A). When HIPPO signaling is turned “on,” LATS (kinase protein), in association with NF2 (membrane-associated protein) and AMOT (scaffold protein), phosphorylates YAP (transcriptional co-activator).

Fig. 5 HIPPO signaling and cell type-specific gene expression. (A) Schematic representations of HIPPO signaling that is differentially regulated between outside and inside cells. Nuclear localization of YAP leads to transcriptional activation of TE-specific genes. (B) Immunofluorescent visualization of YAP (green) and actin filament (red; highlighting cell boundaries) in a cross section of a morula at the 16- to 32-cell stage. Scale bar = 50 μ m.

Phosphorylated YAP is degraded or retained in the cytoplasm, and therefore is functionally inactive. In contrast, when HIPPO signaling is turned “off,” YAP remains unphosphorylated and translocates into the nucleus to associate with TEAD (DNA-binding protein), and together they function as a transcriptional activator. In the mouse embryo before the formation of the blastocyst cavity, HIPPO signaling is turned on in inside cells, but is turned off in outside cells (Fig. 5A and B). As a result, YAP accumulates in the nucleus only in outside cells, and forms a complex with TEAD to activate transcription of TE-specific genes, such as *Cdx2*. Experimental inactivation of HIPPO signaling components causes abnormal expression patterns of TE- and ICM-specific genes. For example, when YAP or TEAD is deficient, expressions of TE-specific genes are abolished and ICM-specific genes are activated in outside cells (Nishioka et al., 2008, 2009). On the other hand, loss of NF2, LATS, or AMOT results in ectopic expression of TE-specific genes in inside cells (Nishioka et al., 2009; Cockburn et al., 2013; Hirate et al., 2013). Therefore, the differential regulation of HIPPO signaling between inside and outside cells is the key to attain cell type-specific gene expression patterns.

The differential activity of HIPPO signaling in relation to cell position is regulated by the apical-basal cell polarity. Whereas inside cells are completely surrounded by neighboring cells, outside cells have the surface that is exposed to the external environment, which allows establishment of the apical-basal polarity. The exposed surface becomes the apical membrane domain, whereas the area adjacent to the neighboring cells becomes the basal membrane domain (Fig. 3). Each membrane domain is populated with unique sets of protein components in a manner similar to the apical-basal polarity found in most epithelial cell types. The components localized to the apical domain are aPKC, PAR3, PAR6, and CDC42, whereas the basal domain components include PAR1, LGL, and SCRIB. aPKC and PAR1 are kinases that modulate the activities of proteins through phosphorylation, whereas the others act as scaffolds to tether proteins to a specific membrane domain. Localization and activity of these polarity proteins are crucial to turn off HIPPO signaling in outside cells (Fig. 5A). For example, when the apical-basal polarity is impaired by experimental disruption of the apical domain (e.g., removal of PAR6) or the basal domain (e.g., removal of PAR1), YAP does not translocate into the nucleus and TE-specific genes are not expressed (Alarcon, 2010; Hirate et al., 2013; Korotkevich et al., 2017). Although the molecular connection between the apical-basal polarity and HIPPO signaling has not yet been fully delineated, a potential mechanism involves localized distribution of AMOT. In outside cells, the apical membrane domain sequesters and possibly inactivates AMOT, leading to the turning off of HIPPO signaling (Hirate et al., 2013). Further investigations are underway to identify other key mechanisms by which the apical-basal polarity influences HIPPO signaling.

Clinical Relevance of the Trophectoderm

The preceding sections are largely based on studies using the mouse as a eutherian model. However, the functional significance and embryological origin of TE are likely to be similar in human. The following section focuses on three specific topics that involve TE and bear clinical significance for human reproduction and fertility.

Early Pregnancy Loss

In human, early pregnancy loss is a common condition characterized by spontaneous abortion or miscarriage of the conceptus before 12 weeks of gestation (Macklon et al., 2002; Larsen et al., 2013). A number of mechanisms have been proposed to cause the miscarriage. One possibility is the abnormal development of the two tissues of the blastocyst, which would result in miscarriage near the time of implantation. For instance, TE development is compromised, and it differentiates into inferior trophoblasts. Normally, healthy trophoblasts secrete the hormone called human chorionic gonadotropin (hCG), which promotes a chain of

molecular events that are essential for the maintenance of the endometrium during the establishment of pregnancy. Since hCG is produced only by the trophoblasts and is excreted in the maternal blood and urine, it is the molecule detected by pregnancy tests. When trophoblasts are defective and fail to produce sufficient hCG, the endometrium degenerates and is shed from the uterus along with the conceptus, thereby terminating the pregnancy. The requirement for proper interactions between trophoblasts and endometrium may serve as a natural screen to select for good quality conceptus. However, TE may also be damaged by exposures to developmental toxicants, resulting in pregnancy loss.

Hydatidiform Mole

In human, the abnormal behaviors of TE are linked to pregnancy-related disorders collectively referred to as gestational trophoblastic disease. The most common type is hydatidiform mole (HM; “hydatid” is from the Greek “hydatidos,” meaning watery vesicle), also known as molar pregnancy or mole. It is a non-viable pregnancy owing to an abnormal blastocyst that overexpresses paternal-derived (i.e., sperm-borne) genes and whose TE gives rise to aberrant placental overgrowth. The ICM may give rise to little or no fetal tissues. According to the United States National Cancer Institute, females in the extreme ends of reproductive age, namely adolescents and perimenopausal women, are at increased risk for HM, affecting 1–3 out of 1000 pregnancies in developed countries.

The placental overgrowth of HM is usually benign, though in rare cases it becomes malignant. Such tumors are unique since they arise from the TE of the conceptus and not from tissue of the maternal body. Patients present with an abnormally high level of hCG secreted by the molar trophoblasts compared to the trophoblasts of a normal pregnancy. Most women can now be cured because of effective anti-neoplastic medications, such as methotrexate, and can have a normal pregnancy after experiencing a molar pregnancy.

HM is classified as complete (CHM) or partial (PHM) based on pathology and genetics (Seckl et al., 2010). CHM is a pregnancy without an embryo and only placental tissues form. The trophoblastic villi of the placenta tend to accumulate fluid and swell, appearing as bunches of grapes. CHM forms from the TE of an unusual blastocyst, the product of an egg that lost its nucleus and is fertilized by two sperm or one sperm whose genome duplicated. While the resulting karyotype is numerically normal (diploid), it is exclusively paternal in origin, and is 46, XX or 46, XY. 46, YY has not been observed since a conceptus with such genetic makeup probably perishes. In rare cases, CHM originates from a conceptus that is biparental but with an abnormal maternal genome that functions like the paternal genome.

PHM, on the other hand, consists of placental overgrowth with patches of swollen trophoblastic villi and some fetal tissues. The blastocyst, in this case, is the product of an apparently normal egg that is fertilized by two sperm. The karyotype is triploid with two sets of paternal-derived genomes in addition to the one set of maternal-derived genome, and is 69, XXX or 69, XXY or 69, XYY.

The occurrence of HM demonstrates that parental genomes are not functionally equivalent owing to the process called imprinting. While paternal-derived and maternal-derived genomes contain the same genes, a parent puts its imprint or biochemical mark on certain genes according to the sex of the parent. The imprint serves to regulate gene expressions, by activating (turning on) or inactivating (turning off) them. Genes required for early placental development are turned on in the paternal-derived genome, and are overexpressed in HM due to the two sets of paternal genomes. In contrast, genes required for early embryonic development are turned on in the maternal-derived genome, and are either absent or underexpressed in HM. The observations with HM are supported by experiments with mouse embryos that were manipulated to contain exclusively paternal genomes or exclusively maternal genomes (McGrath and Solter, 1984).

Trophoctoderm Biopsy

TE biopsy is the sampling of TE cells from the blastocyst produced by in vitro fertilization (IVF) to analyze for the presence of genetic abnormalities (e.g., chromosome defect and single gene defect) or to determine sex (Hyde and Schust, 2015). The procedure is used to aid in the selection of blastocysts for transfer into the uterus of patients undergoing assisted reproductive services.

According to the Centers for Disease Control and Prevention, many people experience problems of fertility in the United States. Such problems are the inability to conceive after 1 year of sexual intercourse with the same partner without the use of contraceptives or the inability to sustain a pregnancy to live birth. Factors that contribute to them originate from either the female or male, or both. Fertility problems are not necessarily symptomatic of sterility, and assisted reproductive technologies (ART) may enable affected individuals to achieve conception and the successful birth of a baby. It is estimated that almost 2% of all babies born annually in the United States are conceived using ART.

IVF is the most commonly used ART. Eggs and sperm are retrieved from the patients, and are combined in a Petri dish. This allows fertilization to take place, and the resulting conceptus is transferred into the uterus for implantation. However, IVF often yields several conceptuses, and patients may decide for them to undergo preimplantation genetic diagnosis (PGD) or screening (PGS) to select only the desired conceptus for uterine transfer. TE biopsy has become a common method for collecting a small number of TE cells for PGD/PGS. During the biopsy, a portion of the mural TE, i.e., the TE covering the blastocyst cavity is aspirated into a pipette, a glass tube with a narrow bore, and is separated from the blastocyst with the aid of a laser device. The collected TE cells are then processed for genetic analyses (e.g., chromosome numbers and structures, and DNA sequences). Although the TE does not become part of the fetal body, it is a suitable proxy for testing since its genetic composition is the same as the ICM.

Due to the hole created in the TE epithelium by the biopsy, the fluid in the cavity leaks out and the roof of the cavity collapses. The biopsied blastocyst is cryopreserved to await the results of the genetic analyses. If a blastocyst is selected for transfer, it is thawed

during which the wound in the TE epithelium closes, and the cavity re-expands. Since the blastocyst consists of more than 100 cells, it is resilient to the removal of a few TE cells and is capable of continuing development to produce a baby.

Glossary

Blastocoel Fluid-filled cavity that forms between ICM and trophoblast.

Blastocyst Mammalian embryo containing a blastocoel.

Blastomere Cell within a cleavage-stage embryo.

Chimera Single organism comprising cells from different zygotes.

Cleavage Cell division in the absence of growth.

Compaction Morphological change of a mammalian embryo from a loose cluster of spherical cells into a tightly packed mass.

Conceptus Product of conception, comprising an embryo and its extraembryonic membranes.

Cytoskeleton Cytoplasmic protein filaments (e.g. actin, tubulin) that shape an eukaryotic cell and direct its movement.

Determination Follows specification. Irreversible process whereby a cell commits to a particular developmental fate if left undisturbed in its environment. Non-determined cells will change their fate if placed in a novel ectopic context but determined (or committed) cells will not.

Differentiation Irreversible changes gene and protein expression to execute specific cellular functions associated with commitment or determination.

Epiblast Pluripotent derivative of the pluriblast or inner cell mass (ICM), giving rise to all embryonic lineages and germ cells.

Epithelium Sheet of polarized cells forming the outer surface of a structure or lining a cavity.

Eutheria Together with prototheria (or monotremes) and metatheria (or marsupials), eutheria (or placentals) form the class of mammals.

Hypoblast Endoderm derivative of the pluriblast or inner cell mass (ICM), giving rise to extraembryonic layers of the yolk sac.

Inner cell mass (ICM) Clump of cells to one side of the blastocyst, entirely enveloped by the trophoblast. In eutherians, the pluriblast is referred to as ICM before segregating into hypoblast and epiblast.

Morula A solid ball of blastomeres contained within the zona pellucida and resembling a mulberry (Latin: morus), preceding the blastocyst stage.

Placenta Transient extraembryonic organ for nutritional supply during pregnancy in mammals.

Pluriblast A group of cells that segregates into hypoblast and pluripotent epiblast, referred to as inner cell mass (ICM) in eutherians.

Pluripotency Ability of a cell to form all embryonic lineages and germ cells.

Specification Reversible process of restricting developmental potential of a cell to a certain fate. It precedes determination and differentiation.

Totipotency Ability of a cell to form a viable animal on its own.

Trophectoderm (TE) Trophoblast epithelium enclosing the ICM in eutherian blastocysts, giving rise to extraembryonic parts of the placenta.

Trophoblast Extraembryonic ectoderm adapted for trophic functions, i.e. taking up nutrients via the placenta, in mammals.

Zona pellucida A proteinaceous extracellular coat that surrounds the developing embryo from the oocyte to the late blastocyst stage.

Zygote A diploid cell formed when two haploid gametes fuse.

Mammalian Preimplantation Development

The natural mammalian life cycle begins with fertilization when two haploid gametes fuse to form one diploid zygote. This single cell can give rise to a viable organism on its own, a property referred to as totipotency. The zygote undergoes a series of DNA replications and cleavage divisions, partitioning its cytoplasm into progressively smaller nucleated daughter cells, called blastomeres, without increasing total embryo volume (Fig. 1; Aiken et al., 2004). As the number of cells in the embryo increases from one to two to four and so on, their average nucleo-cytoplasmic ratio increases exponentially (Aiken et al., 2004). After a few cleavage divisions, the blastomeres compact and form a tight morula. This structure is unique to some placental mammals and comprises an outer layer and an internalized cell mass. The outer cells become the first fully functional epithelium of the conceptus, channeling water and ions inside to form a small fluid-filled cavity, the blastocoel. Cavitation marks the appearance of an early blastocyst, a hollow ball of cells with an outside single cell trophoblast layer, often called trophectoderm (TE), enclosing a small inner cell mass (ICM) to one side of the expanding blastocoel. This first lineage decision defines the polarity axis of the blastocyst, with an embryonic pole, marked by the ICM, and an opposite abembryonic pole. As development proceeds, the trophoblast gives rise to fetal placenta, while the ICM segregates into the hypoblast (or primitive endoderm), fated to form the extraembryonic endoderm layers of the yolk sac, and the pluripotent epiblast, which develops into all intraembryonic lineages, including germ cells,

Fig. 1 Overview of mouse preimplantation development. Schematic cross-sections of embryos undergoing cell division, morphological change and lineage segregation from the zygote to the blastocyst stage. Blastomere heterogeneity appears at the 4-cell stage, with the first lineage decision separating inner (pale green) and outer cells (pale orange) in the morula. The ICM (green) appears transiently within the expanding TE (orange) before differentiating into epiblast (dark green) and hypoblast (pale blue) lineages.

and extraembryonic yolk sac mesoderm. The blastocyst then hatches from its surrounding extracellular coat, the zona pellucida, and is ready to attach to the uterus, ending the period of preimplantation embryogenesis.

Principles of Development: Preformation vs Epigenesis

In principle, emergence of the ICM can be explained by two abstract concepts known as preformation (or mosaic) and epigenesis (or regulative) modes of development (Solter, 2016). Pure mosaic development would require the precise localization and heterogeneous distribution of fate-guiding determinants in the zygote, whose presence or absence in parts of the developing embryo will then exactly predict their respective future fate. Many non-mammalian model species (e.g. *Caenorhabditis elegans*, *Drosophila melanogaster*, *Xenopus laevis*) largely follow this invariant pattern. By contrast, pure regulative development would require a homogeneous zygote whose development is solely governed by responding to external factors, such as diffusible intercellular signals, positional information and cell–cell interactions. However, there is probably no organism that exclusively follows one or the other of the two stereotypical modes. Consequently, the distinction between these contradictory models has been somewhat softened by distinguishing “stochastic” from “biased” modes of development. The former argues that early embryonic cells are equipotent and differentiate as a consequence of random processes, whereas the latter poses some heterogeneity between blastomeres resulting in early developmental bias. In reality, mammalian development likely follows a mixed mode, encompassing both deterministic prepatterning and probabilistic regulative elements, creating developmental bias from gradual amplification of small, random heterogeneities.

The Mouse Embryo as a Model for ICM Development

Mammalian embryology is dominated by the study of one species, *Mus musculus*. This small eutherian (placental) animal with its rapid life-cycle and large litter size has supplied the foundation of our understanding of mammalian reproductive physiology and development. The following summary will proceed chronologically through murine ICM development, focusing on cellular and molecular changes between blastomeres that guide fate decisions. It is based on several recent reviews that chronicle the events in greater detail (Leung et al., 2016; Graham and Zernicka-Goetz, 2016; Chazaud and Yamanaka, 2016).

Precompaction Blastomeres and Early Bias in ICM Fate

Early mouse embryos can respond flexibly to compensate for a variety of experimental perturbations. For example, dissociating embryos at the 2-cell and 4- or 8-cell stage results in morphologically identical single blastomeres, some of which can develop into entire animals and contribute to all tissues in chimeras, respectively. Since in any given experiment not every blastomere shows such remarkable developmental plasticity, these observations are compatible with both stochastic and biased views of development (Solter, 2016). Conclusive evidence that the two sister blastomeres of a 2-cell embryo inherit significantly different amounts of proven fate determinants, such as RNA transcripts, has so far been elusive.

By contrast, specific transcriptional and epigenetic heterogeneities have been identified at the 4-cell stage (Fig. 2). The first molecular difference between individual blastomeres relates to the epigenetic modifier *Prdm14* whose mRNA and protein expression is transiently restricted to only two blastomeres at the late 4-cell stage. Its abundance correlates with histone (H) 3

Fig. 2 Molecular heterogeneities bias ICM specification in mouse 4-cell embryo. Increased PRDM14 levels in two blastomeres start off a cascade that promotes the ICM lineage. PRDM14 interacts directly with CARM1 to increase H3R26me2. This correlates with increased DNA-binding of OCT4/SOX2, upregulating SOX21 and biasing blastomeres towards ICM. This hypothetical model possibly also involves *Prdm14* suppressing *Dnmt3b* and *Dnmt3l* expression. By contrast, lack of PRDM14 and CARM1 activity in another blastomere results in low H3R26me2. Along with decreased OCT4/SOX2 DNA-binding and increased *Dnmt3b/Dnmt3l* expression, this biases towards a TE fate.

arginine (R) 26 di-methylation levels (me2), which are also heterogeneous at this stage, predisposing low H3R26me2 blastomeres towards developing into TE derivatives. H3R26me2, in turn, is catalyzed by CARM1, a direct interaction partner of PRDM14. In ectopic overexpression studies, both *Prdm14* and *Carm1* can increase H3R26me2 levels and promote ICM fate. Expression of *Prdm14* is mutually exclusive with that of de novo DNA methyltransferases *Dnmt3b* and *Dnmt3l* in 4-cell embryos. This inverse correlation of expressing epigenetic modifiers is carried through to mid-blastocysts, where *Prdm14* and *Dnmt3b/Dnmt3l* transcripts become transiently ICM- and TE-enriched, respectively. This is consistent with *Prdm14* directly suppressing *Dnmt3b* and *Dnmt3l* expression. Furthermore, CARM1 activity and H3R26me2 levels are positively correlated with abundance of the transcription factor *Sox21*. *Sox21* is a downstream target of *Oct4* and *Sox2*, ICM-specific master regulators of pluripotency, that both antagonize *Cdx2*, a master regulator of TE formation. The findings tie in with heterogeneous DNA-binding dynamics of OCT4 and SOX2 in 4-cells, whereby those blastomeres that have long-lived DNA interactions, indicative of increased OCT4/SOX2-binding and transcriptional activity, are biased towards ICM (White et al., 2016). The same blastomeres that retain stable SOX2-DNA binding also display higher CARM1 and H3R26me2 levels (White et al., 2016).

Together, these findings suggest that individual blastomeres within a subset of 4-cell embryos already display molecular identifiers of the future ICM and exhibit a skewed contribution towards this lineage. However, it remains to be shown that prepatterned variability in the endogenous levels *Prdm14*, OCT4/SOX2-binding and *Sox21* is sufficient to cause a bias towards ICM fate in subsequent cell divisions. It is also unknown how such variability is mechanistically established in the first place.

Compacting Morula: Changes in Cell Shape, Polarity and Position

The 8-cell stage embryo is a symmetrical ball of relatively spherical cells, all morphologically indistinguishable from each other. This appearance drastically changes with the key morphogenetic event that takes place next: compaction. During compaction, all eight blastomeres elongate, flatten and adhere tightly together, eliminating intercellular spaces and minimizing the surface area of the now densely packed embryo. This change in embryo shape is so evident that it can be readily visualized with a standard stereomicroscope. At the same time, each blastomere polarizes into a conventional epithelial structure, containing an outside apical domain and an inside basolateral domain. The apical membrane is typically enriched in surface microvilli and a network of underlying cytoskeletal elements, including actin, myosin and α -tubulin, as well as secretory organelles. The basolateral surface accumulates various cell-cell contacts, including gap, adherens and later tight junctions. These changes in cell shape and polarity critically rely on E-cadherin, a highly conserved calcium-dependent transmembrane adhesion molecule. Without any E-CADHERIN to increase cell-cell contact and initiate compaction, cells continue to divide but only create partially polarized, rounded cells that are loosely attached to one another. Even though they do not form a functional TE epithelium, these aggregates express high levels of the TE specifier *Cdx2*. Individual cells still generate an apical membrane domain, which elevates *Cdx2* expression by suppressing Hippo signaling (see below). Moreover, *Cdx2* mRNA is normally apically anchored. Its dislocation leads to inside cells ectopically expressing this fate-guiding factor, which compromises ICM development. At the same time, low levels of the ICM specifier *Oct4* and absence of spatially segregated ICM cells indicate that E-cadherin normally creates a permissive context for future ICM development. This demonstrates how closely cell polarization is linked to guiding formation of the prospective ICM vs TE lineages.

Importantly, the first acquisition of polarity coincides with changes in cell position that predict cell fate. It results in blastomeres that can divide in different orientations with respect to their apicobasal axis: either symmetric (with the plane of division parallel to the axis of polarity), giving rise to two daughter cells that both remain outside and inherit parts of the apical domain; or asymmetric (with the plane of division perpendicular to the axis of polarity), giving rise to one polar outside daughter cell that retains the complete apical domain and one apolar inside cell. Classic views, embodied in the so-called “inside-outside” (Tarkowski and Wroblewska, 1967) and complementary “polarization” (Johnson and Ziomek, 1981) hypotheses assumed that symmetric divisions produce only future TE (outside) cells, while asymmetric divisions will also produce one future ICM (inside) daughter cell. These orientated cell divisions had been inferred on theoretical grounds and analysis of fixed specimen. Recent advances in live imaging have enabled quantitative tracking of changes in cell shape and position that are central to ICM formation, leading to a revision of the traditional models (Samarage et al., 2015). Asymmetric cell divisions were rare events and internalization occurred when the first outside cell lost its apical domain by shrinkage of the exterior surface, usually at the 12-cell stage. This “apical constriction” mechanism is commonly used during animal development and tissue morphogenesis. It relies on mechanical forces mediated by E-cadherin adhesion and produced by contractile actomyosin tension from apical the cell surface (Samarage et al., 2015). Thus anisotropies in cortical tension, not oriented cell division, may first spatially segregate cells within the mouse embryo. Important questions that remain to be answered are when the asymmetries in cortical tension between cells arise, how they affect polarized fate guides (e.g. *Cdx2*) and to what extent they originate from predetermined or random heterogeneities in biomechanical properties of neighboring cells.

Post-Compacting Morula and ICM Specification From Inner Cells

At the 16-cell stage, the mouse embryo contains on average three inside cells (Samarage et al., 2015), which are smaller and have larger nucleo-cytoplasmic ratios than the outside cells (Aiken et al., 2004). This spatial segregation creates two discrete niches, exposing inner and outer cells to different microenvironments and cell-cell contacts. Once these subpopulations of inside vs

outside cells have been firmly established in the morula, their different cell positions instruct differences in cell signaling, transcriptional activity and ICM vs TE specification.

The main pathway known to coordinate these activities is Hippo signaling, named after its key signaling component, the protein kinase Hippo (MST1/2 in mammals). This evolutionary conserved kinase cascade regulates cell number by modulating cell proliferation, cell death, and cell differentiation. In flies, deletion of any Hippo pathway component leads to “hippopotamus-like” tissue overgrowth but mutant mice show more complicated phenotypes. In the context of the early mouse during embryogenesis, Hippo signals can integrate changes in cell shape and position through sensing both mechanical inputs, such as actomyosin rearrangements, and polarity information. When Hippo signaling is active in inner cells, transcriptional co-activators YAP and TAZ remains cytoplasmic, leading to the expression of ICM genes, such as *Oct4*, *Sox2* and *Nanog* (Fig. 3). In the absence of Hippo signals in outer cells, YAP/TAZ transcriptionally co-activate TE master regulator *Tea4* and its downstream target *Cdx2*. Thus quantitative CDX2 protein expression can be used as an accurate readout of Hippo signaling activity and the process of ICM/TE specification (Posfai et al., 2017).

Activation of Hippo signaling depends on basolateral cell–cell junctions and the absence of an apical membrane domain, which are conditions only found in internalized cells. How does lack of an apical domain activate Hippo signaling in inner cells while presence of an apical domain suppresses it in outer cells? The answer lies in sequestration of key members of the pathway by proteins that regulate adhesion and polarity. AMOT and NF2 are required to activate Hippo kinases LATS1/2 and switch on Hippo signaling. AMOT and LATS1/2 kinases are both inactive as long as they are apically localized, preventing activation of the Hippo pathway in outer cells. In inner cells, which lack an apical domain, AMOT localizes to adherens junctions, interacting with E-cadherin via NF2 and binding LATS1/2. LATS1/2 then phosphorylates and activates AMOT at the adherens junctions, in turn phosphorylating YAP/TAZ. Phosphorylated YAP/TAZ is excluded from the nucleus and degraded. Consequently, YAP/TAZ cannot

Fig. 3 Hippo signals coordinate cell position, polarity and lineage specification in mouse morula. Inner and outer cell lineage specification is mediated by Hippo signaling. In polarized outer cells, Hippo signaling is “turned off” by the apical membrane (blue) sequestering AMOT and LATS1/2, allowing YAP/TAZ co-activation of TEAD4. In inner cells without an apical membrane, LATS1/2 is free to phosphorylate AMOT, “turning on” Hippo signaling by allowing association with NF2 on basolateral membranes (pink). Phosphorylation excludes YAP/TAZ from the nucleus and allows transcription of ICM genes.

co-activate TEAD4, resulting in failure to induce the TE program via *Cdx2* expression. In this way, inner cells switch on Hippo signals to inactivate YAP/TAZ and allow expression of ICM genes. Without any NF2, the Hippo pathway cannot be activated and such embryos fail to form an ICM. Regardless of their position, inner cells then revert to expressing TE genes instead. In summary, cell position and polarity are mutually reinforcing properties. Hippo signals consolidate differences in cell polarity and position through transcription factor activation, driving the first lineage bifurcation by converting inside cells into ICM and outside cells into TE.

The relationship between cell polarity and cell fate has been further probed by sequentially separating blastomeres after each cell division from the 2-cell to the 32-cell stage, thereby completely inhibiting cell–cell contact and positioning (Lorthongpanich et al., 2012). Each singled out cell adopts a unique gene expression pattern, representing a random mixture of ICM- and TE-specific genes, but overall leaning towards a TE-like profile. Isolated cells also preferentially contribute to TE in morula aggregation experiments. This is consistent with early observations that isolated 8-cell blastomeres give rise to functional TE but do not form ICM-derivatives. On their own, these blastomeres depolarize and consequently activate Hippo/YAP signaling. However, such blastomeres still become biased towards TE, despite the loss of apicobasal polarity and active Hippo signals. Thus lack of an apical domain and Hippo signals are insufficient to entirely control the first lineage decision and induce ICM commitment. Collectively, these data suggest that cell–cell interactions and positional information provide additional cues that are important for correct cell fate specification.

After the 16-cell stage, inner cells expand in numbers while retaining their internal position. At the same time, new inner cells continue to be added by apical constriction and asymmetric divisions of outer cells (Samarage et al., 2015).

Blastocyst Formation and ICM Lineage Segregation

By the 32-cell stage, the nucleo-cytoplasmic ratio of the outer cells has stabilized, marking the end of cleavage division for this subpopulation (Aiken et al., 2004). There is a clear distinction between the apolar inside cells and the outside epithelial monolayer and these divergent compartments herald the formation of the first two lineages: ICM and TE. For cells expressing CDX2, cell fate is basically sealed at this stage, and they are unable to give rise to the ICM. ICM cells, on the other hand, delay their commitment to the next two lineages by another cell cycle, up until some point between the 32- and 64-cell stages (Posfai et al., 2017).

Mouse blastocyst formation starts around the 32-cell stage when the outer morula cells form a fully functional epithelium. The combined presence of tight junctions, sodium and water channels results in the accumulation of liquid within the embryo and formation of the blastocoel cavity. Once cavitation has begun and the ICM appears at the embryonic pole of the cavity, the embryo is referred to as an early blastocyst. At this stage, individual ICM cells are still undergoing cleavage and are not distinguishable by volume or nucleo-cytoplasmic ratio (Aiken et al., 2004). They remain developmentally flexible and can engender all embryonic and extraembryonic lineages. For example, isolated early ICM cells are able to redevelop into miniature blastocysts and contribute to TE after morula complementation. This ability is lost when the ICM number exceeds 16–19 cells, concomitant with end of cleavage divisions and start of the second lineage bifurcation into inner epiblast and outer hypoblast. Each ICM cell becomes irreversibly committed to either epiblast or hypoblast within a single cell cycle (Posfai et al., 2017), coinciding with the end of cleavage divisions and initiation of cell growth, replicative proliferation and stable nucleo-cytoplasmic ratios (Aiken et al., 2004). Perhaps it is no coincidence that ICM cells make their next cell fate choice at the same time. In contrast to the earlier ICM/TE specification, this second lineage decision does not appear to be primarily position-dependent but rather relies on cell–cell signaling (Fig. 4). Early ICM cells co-express epiblast markers, such as SOX2 and NANOG and early hypoblast markers, such as GATA6 and PDGFR α , making the transcriptomes of individual ICM cells at the 32-cell stage indistinguishable. These opposing lineage specifiers are in

Fig. 4 ICM differentiates into epiblast and hypoblast in mouse blastocyst. In epiblast (EPI) progenitors (green), NANOG drives expression of *Fgf4* while also repressing *Gata6*. Secreted FGF4 then signals through FGFR2 on the surface of hypoblast (HYPO) progenitors (light blue) to activate *Gata6* and repress *Nanog*.

a delicate balance that will gradually tip towards complete lineage segregation within the next few hours. In mouse, this process is mainly driven by FGF4, a secreted factor that is autocrinally produced in nascent epiblast cells. While epiblast progenitors are temporarily unresponsive to the FGF ligand they secrete, nearby hypoblast progenitors express the cognate FGF receptor 2 (FGFR2) and respond by upregulating GATA6 and downregulating NANOG expression (Lanner and Rossant, 2010). Blastocysts carrying a genetic deletion of *Fgf4* or its downstream signaling components do not maintain early hypoblast-specific transcription factors and consequently lack hypoblast (Lanner and Rossant, 2010). Conversely, administering exogenous FGF4 to early embryos sustains expression of hypoblast markers and inhibits epiblast-specific NANOG. As a result, the entire ICM forms hypoblast in a dose-dependent manner (Lanner and Rossant, 2010). Taken together, continuous FGF4-FGFR2 signaling drives stable epiblast/hypoblast segregation and regulates the cell number ratio of these two tissues in the mouse embryo. By the 64-cell or mid-blastocyst stage, segregation of the two lineages is consolidated with the top three inversely correlated gene pairs within the ICM being (i) *Fgf4*, *Nanog* and *Sox2* for the epiblast and (ii) *Fgfr2*, *Gata6* and *Gata4* for the hypoblast, respectively. *Nanog* expression, in particular, is tightly correlated with the nascent epiblast and mutually exclusive with the hypoblast marker *Gata6*. Initially, these markers are expressed in a mutually exclusive “salt and pepper”-like distribution throughout the ICM, before sorting into their correct positions through a combination of cell migration and selective apoptosis.

It is still controversial which developmental mode best explains how binary heterogeneities first arise during ICM differentiation. In the stochastic model, random fluctuations in gene expression, followed by positive feedback and reciprocal repression, are sufficient to explain lineage divergence. Alternatively, cell division history may bias cell fate, with cells being internalized during the 4th (8–16 cell) vs 5th (16–32 cell) and 6th (32–64 cell) cleavages becoming predominantly epiblast vs hypoblast, respectively. The strength of this bias was correlated with relative levels of FGF-producing and -responding internal cells having a dose-dependent effect on ICM composition. Sequential waves of internalization could provide a mechanism for specifying three different lineages (tropho-, epi- and hypoblast) from only two different positional states (in-, outside). However, this internalization time-dependent bias does not preclude stochastic differences. As embryogenesis is a highly regulative and dynamic process, any molecular lineage biases between early vs late entering cells may be subtle and readily overridden by exogenous factors, such as modulation of FGF signaling.

By the late blastocyst stage, two groups of inner cells are morphologically distinguishable: the epithelial hypoblast forms a monolayer facing the blastocoel, covering the surface of an apolar pre-implantation epiblast cluster. Once these two lineages are irreversibly committed, the foundations to all embryonic and extraembryonic lineages are laid and the embryo starts to attach to the uterine endometrium. At that point, the transitory ICM compartment, which in mouse only lasts for just over a day (3.25–4.5) and a couple of cell cycles, has ceased to exist.

Whilst there is compelling evidence that differentiated ICM cells can be permanently captured in vitro, either as hypoblast-derived extraembryonic endoderm or as epiblast-derived naïve pluripotent embryonic stem (ES) cells, this has not yet been achieved with early ICM cells. Compared to epiblast and ES cells, which can self-renew in vivo and in vitro, respectively, it may be more challenging to in vitro culture non-committed, cleavage-stage ICM blastomeres, which do not normally self-renew in vivo (Boroviak and Nichols, 2014).

Evolutionary Context of ICM Development

Mus musculus only represents 0.02% of the existing 5488 mammalian species. In addition to placental eutherians, the class of mammals comprises prototheria (monotremes), which share many developmental features with reptiles and birds, and live-bearing metatheria (marsupials). All three groups develop a functional placenta, but marsupials and placentals rely more heavily than monotremes on this transient extraembryonic organ for nutritional supply during pregnancy. The placenta ultimately derives from the trophoblast, while all other tissues derive from the pluriblast, only referred to as ICM when it is entirely enveloped by the trophoblast, as in the case of eutherians. Thus, strictly speaking, the ICM is an invention of placental mammals. Whilst there are broad similarities between mice and the remaining 99.98% of extant mammals, some critical features of murine preimplantation development are not representative for the phylogenetic group as a whole (Fig. 5), as discussed in more detailed reviews (Sheng, 2015; Frankenberg et al., 2016).

Non-Rodent Eutherians

The chronological sequence of early development is similar between rodents (mouse, rat) and a large number of taxonomically diverse placental orders, such as primates (human, marmoset, macaque), artiodactyls (cow, sheep, deer, pig) and carnivores (cat, dog). This includes key morphogenetic events, such as compaction, inside-out morulation, cavitation, ICM formation and hypoblast-epiblast segregation. However, the timing of cleavage, compaction, blastulation and concomitant lineage specification differs, with the interval between zygote and blastocyst formation taking about 1 week in some species (e.g. cow, pig) compared to 4 days in mouse.

Early embryogenesis in afrotherians, the first group to split from the placental tree, is quite different. Members of this clade, such as elephant shrews or tenrecs, clearly diverge from the rodent prototype. Both species start cavitation at the 4-cell stage, preceding blastomere internalization that would normally occur during morula formation. Skipping the morula stage, a precocious trophoblast-like vesicle with no discernible ICM forms as early as the 16-cell stage. Even though this “blastocyst” resembles

Fig. 5 Comparative mammalian ICM development. (A) Mammalian phylogenetic tree of representative eutherian, prototherian and metatherian species (www.timetree.org). (B) Early embryonic development before apparent ICM vs TE lineage segregation (left column), during formation of a discernible ICM or ICM-equivalent (center column), and after ICM differentiation (right column). Prototherian embryos contain yolk (*pale yellow*) instead of a blastocoel. Embryos are not drawn to scale.

a unilaminar trophoblast epithelium, its cells do not appear to be restricted to the trophoblast fate and will give rise to both epiblast and hypoblast precursors. In the tenrec, epiblast and hypoblast precursors preferentially delaminate from one pole of the trophoblast monolayer, while in the elephant shrew delamination appears to occur randomly. In both cases, the internalized precursors then aggregate and segregate into a similar late ICM structure as in the mouse, with the epiblast mass being sandwiched between the basal sides of polar trophoblast and hypoblast epithelia.

Marsupials

Marsupials are a sister group of placental mammals and their embryo development has been studied in over a dozen species. They all form a trophoblast-like blastocyst, in which individual epithelial cells surround a central blastocoel but lack an ICM. Like in the

tenrec, the precursors of epiblast and hypoblast are restricted to one pole of this unilaminar structure, forming the pluriblast as part of the continuous trophoblast epithelium. Orthologues for key fate specifiers, such as OCT4, SOX2, NANOG, YAP and CDX2 are not differentially expressed, suggesting that these factors are not involved in trophoblast-pluriblast lineage segregation. By the late unilaminar stage, blastocyst cells become molecularly and morphologically heterogeneous with juxtacoelic pluriblast cells adopting a columnar epithelial shape and expressing nuclear-localized NANOG, while GATA6-expressing hypoblast cells delaminate from the pluriblast region. These internalized hypoblast cells migrate to cover both the epiblast, i.e. the non-delaminating remainder of the pluriblast, and the trophoblast, forming a bilaminar structure with three well-defined cell lineages.

Monotremes

Extant monotremes (echidnas and platypuses) represent an early branch of mammalian evolution and they retain ancestral features of reptilian embryogenesis. Knowledge about their early development is limited to just a handful of classical papers and recent interpretations. Monotreme oocytes are an order of magnitude larger in diameter than those of other mammals and contain a large amount of yolk. Cleavage divisions do not divide the embryo completely and result in an embryonic-abembryonic axis that corresponds to the future dorsoventral axis of the embryo. A single cell epithelium eventually covers the entire yolk, the topological equivalent of the blastocoel, forming a blastocyst-like structure. The peripheral monolayer becomes trophoblast, while cells located in the central area of this unilaminar “blastocyst” are specified as future epiblast and hypoblast. These central cells may either still be bipotential precursors or already specified, equivalent to the salt-and-pepper pattern of the mid-ICM or marsupial pluriblast. Similar to marsupials, hypoblast cells then delaminate from the central area and spread on the epiblast and trophoblast surface, forming a bilaminar structure.

Epiblast Development

Formation of the Mammalian Blastocyst

After fertilization of a mammalian oocyte, the formed totipotent zygote starts a series of cleavage divisions. During the first divisions the blastomeres remain totipotent, but this potential gradually decreases upon further development with the timing of developmental restriction dependent on the animal species. The first lineage segregation that occurs is the formation of outer and inner cells around the morula stage. The outer cells form an epithelial sheet of trophectoderm that is important for implantation into the uterus, the fetal maternal interaction and formation of the non-maternal components of the placenta. Pump-like proteins within this epithelium facilitate the formation of a fluid filled cavity, called blastocoel, transforming the embryo into a blastocyst. At this stage the embryo consists of two cell types, an outer trophectoderm layer and an inner cluster of cells referred to as inner cell mass (ICM) facing the blastocoelic cavity. The POU transcription factor OCT3/4 is expressed at high levels in the ICM and is critical for the formation of the pluripotent cell population in the early embryos, while the trophectoderm cells express relatively high levels of the transcription factor CDX2. OCT3/4 and CDX2 not only function as transcription factors, but also as repressors of each other's gene transcription. It is the ICM that will give rise to the epiblast.

Second Lineage Segregation

After the first lineage segregation a second cell fate specification event occurs that segregates the ICM into epiblast, also called primitive ectoderm, and hypoblast, also called primitive endoderm. In the mouse embryo the primitive endoderm after implantation differentiates further to visceral endoderm. The epiblast consists of pluripotent cells that will form the fetus while the primitive endoderm, an amniote specific cell type, although originating from the ICM will predominantly give rise to extra-embryonic tissues such as the yolk sac that provides nutrients to the embryo. During gastrulation most of the visceral endoderm disperses as the epiblast-derived definitive gut endoderm intercalates (Kwon et al., 2008). The primitive endoderm is not only important for its nutritional role as yolk sac, but it also plays an essential role in the organization of the epiblast and therefore the establishment of the body plan.

The transcription factors NANOG and GATA6 control the second lineage segregation of the ICM. Initially, from the 8-cell stage onwards, both transcription factors are present in blastomeric nuclei. Soon after formation of the ICM however, NANOG and GATA6 display a mutually exclusive "salt and pepper"-like expression pattern, with some ICM cells expressing predominantly NANOG while other ICM cells predominantly express GATA6 (Chazaud et al., 2006). This distribution of NANOG and GATA6 appears to be stochastic in a position-independent manner. NANOG-expressing cells will sort out to become the pluripotent epiblast, while GATA6 expressing cells will form an epithelial layer of primitive endoderm overlying the NANOG-positive epiblast and facing the blastocoel. Indeed mice with a genetic deletion for *Gata6* initially do form primitive endoderm but this fails to be specified. After segregation the cells also become morphologically distinct. In mice, the dose of GATA6 in the early ICM regulates the specification of primitive endoderm as demonstrated by a reduction of primitive endoderm cells in *Gata6* heterozygous embryos and defective primitive endoderm in null mutants of *Gata6*. Conversely, mouse embryos genetically deficient for *Nanog* fail to form pluripotent epiblast cells and only produce primitive endoderm cells, besides TE (Mitsui et al., 2003). GATA6 and NANOG repress each other's transcription, and GATA6 seems to be working as an on/off switch since NANOG levels do not increase in the absence of GATA6 (Schrode et al., 2014). After initial expression, the decision for exclusive *Nanog* or *Gata6* expression is subsequently driven by fibroblast growth factor (FGF) and mitogen-activated protein (MAP) kinase signaling. Pre-implantation mouse embryos treated with an inhibitor of FGF receptor activity or an inhibitor of MAP kinase signaling blocked primitive endoderm formation, with all ICM cells expressing NANOG. When embryos were on the other hand cultured in the presence of FGF4, all ICM cells became GATA6-positive (Yamanaka et al., 2010). Exposure of *Gata6* null mutants to exogenous FGF4 could not restore the specification of primitive endoderm, indicating that GATA6 is required for primitive endoderm specification by FGF signaling (Schrode et al., 2014).

In other mammals such as cattle and humans, NANOG and GATA6/GATA4 are initially also expressed in the precursors of epiblast and primitive endoderm in a similar "salt-and-pepper" expression pattern, and later in the epiblast and primitive endoderm respectively after segregation. The signals that regulate NANOG and GATA6 expression are different however. The formation of human GATA6-positive primitive endoderm is for instance not dependent on MAP kinase signaling (Kuijk et al., 2012). In bovine embryos, inhibition of MAP kinase signaling only partially inhibited primitive endoderm formation indicating that although FGF/MAP kinase signaling inhibits NANOG expression, other signals directly stimulate GATA6 expression.

Exactly when the cells are irreversibly committed to either epiblast or primitive endoderm is not known. ICM cells of mouse embryos exhibited plasticity in their developmental fate even after they had established exclusive NANOG or GATA6 expression (Yamanaka et al., 2010). Isolated cells from the epiblast of day 4.5 post-coitum mouse embryos contribute to epiblast or derivatives when injected into the blastocoelic cavity of a host blastocyst, and primitive endoderm cells will only give rise to extra-embryonic endoderm, indicating that at this time epiblast and primitive endoderm are already committed to their lineages. Experiments with

bovine embryos revealed that cells are remarkably flexible and can change fate from becoming NANOG-expressing to GATA6-expressing and vice versa at least until the late blastocyst stage, at day 8 of in vitro culture (Kuijk et al., 2012).

X-Chromosome Inactivation

Sex determination in mammals, with exception of that in monotremes, is determined by the sex chromosomes with homozygous XX in females and heterozygous XY in males. The Y chromosome is much smaller and contains fewer genes than the X chromosome, which could lead to an overexpression of X-linked genes in females. A solution for this phenomenon is a type of dosage compensation by inactivation of one of the X chromosomes in female cells. Central in X-chromosome inactivation is the long noncoding RNA *Xist* that is expressed from the X-chromosome that is to be silenced. *Xist* accumulates on the X-chromosome from which it is expressed and recruits remodeling complexes that repress transcription from this chromosome.

In female cleavage stage mouse embryos, imprinted inactivation of specifically the paternal X-chromosome occurs. At the blastocyst stage, X chromosome reactivation takes place such that in the inner cell mass both X-chromosomes are active in female embryos. Upon formation of the epiblast, X-chromosome inactivation is reestablished but this time in a stochastic fashion in the epiblast and derivatives thereof. In the mouse conceptus, imprinted paternal X chromosome inactivation is maintained in the trophoctoderm and primitive endoderm.

The pattern of X-chromosome inactivation in different mammalian species seems to vary in the cleavage stages, but in the epiblast of most studied species random X-chromosome inactivation takes place (Dupont and Gribnau, 2013). Differences between species are mostly prominent in the lineages that are not derived from the epiblast in particular the trophoctoderm and primitive endoderm. It has been suggested that in mice, rats and cattle the X chromosome inactivation is imprinted in the extraembryonic lineages, while in primates, including human, rabbit and equine species, inactivation of the X chromosome in non-epiblast derived tissues is also random (Dupont and Gribnau, 2013).

Organization of the Epiblast

Before the formation of the definitive fetal germ layers during gastrulation, the human embryo already has implanted into the uterine tissue, making it less accessible for research, and therefore limited information is available regarding this species. In that respect embryos from species such as cattle or horse are more accessible, but high breeding and housing costs together with limited genetic and biochemical tools are disadvantages of these species. Most of the data available on epiblast differentiation therefore have come from studies with mice. In addition, genetic manipulation of pluripotent embryonic stem cells combined with chimaera formation has enabled the generation of gene knock-out and knock-in mice which has substantiated enormously to our current understanding of gene function and pattern formation in the mouse.

The epiblast of mouse embryos forms a radially symmetric cup of epithelial cells, with the extraembryonic ectoderm as an inverted cylinder on top and surrounded on the outside by a single-cell layered visceral endoderm, a derivative of the primitive endoderm (Fig. 1A). The epiblast of most mammals including humans is formed as a flat epithelial sheet of cells, similar to the epiblast of chicken embryos, with the primitive endoderm adjacent/underneath, hence the alternative name hypoblast (Fig. 1B). Up until this stage the epiblast is still radially symmetric, but for induction of the definitive germ layers the establishment of anterior-posterior polarity is essential.

The first sign of anterior-posterior polarity of the conceptus has been detected in the primitive/visceral endoderm of mouse embryos. This axial information in the endoderm is subsequently translated to the epiblast. The endoderm furthest away from the extraembryonic region, the distal visceral endoderm (DVE), derives from a few cells expressing both *Gata6* and *Lefty1* in the late blastocyst. The position of these cells most likely indicates the future mid-anterior side of the conceptus (Takaoka and Hamada, 2012). These cells and progenitors move proximally towards the proximal anterior part of the egg cylinder, triggering global movement of the visceral endoderm. Distal visceral endoderm cells will subsequently lose *Lefty1* expression and migrate laterally-distally away from the proximal anterior region. Simultaneously, prospective anterior visceral endoderm (AVE) cells are newly induced at the distal part of the egg cylinder and migrate towards the anterior side. The function of the DVE is not well known, while the role of AVE in patterning the epiblast has been well established.

The proximal epiblast starts to express proteins such as NODAL and WNT3a. Initially, NODAL is expressed throughout the entire epiblast. The AVE cells on the other hand secrete the NODAL inhibitors LEFTY1 and CER1 and the Wnt inhibitor DKK1, and since Wnt and NODAL are not repressed in the posterior part an anteroposterior axis is established in the epiblast (Perea-Gomez et al., 2002). WNT3A and NODAL in the proximal-posterior part of the epiblast induce expression of the T-box transcription factor BRACHYURY and delamination of epiblast cells through the primitive streak to form the definitive germ layers.

Non-Rodent Species

Compared to early cup-shaped embryos of mice and rats, embryos of other species, including the human, have a sheet-like appearance, much more resembling a peri-gastrulating chick embryo. In the mouse embryo the part of the trophoctoderm that

Fig. 1 Schematic representation of lineage specification in developing mouse (A) and human (B) embryos. E refers to embryonic day; proximal (pr)–distal (di) and anterior (a)–posterior (p) axes are indicated. In the human embryo the anterior–posterior axis is perpendicular to the image.

is in contact with the inner cell mass, the polar trophectoderm, grows out to become the extra-embryonic ectoderm. In various species however, including rabbits, ungulates, cats and dogs, the trophectoderm overlying the epiblast is referred to as Rauber's layer and will degenerate. After disappearance of the Rauber's layer, the epiblast is directly exposed to the uterine milieu and connects laterally with the remaining mural trophoblast to form a continuous sheet. In other animals that form a sheet-like epiblast, such as primates, the polar trophectoderm establishes the connection with the uterine epithelium for implantation.

Most information from the epiblast of non-rodent species comes from ungulates such as the pig and cattle. At the pre-implantation state the sheet-like epiblast of ungulates forms a pseudostratified epithelium with tight junctions, desmosomes and a clear basement membrane separating it from the hypoblast (Hall et al., 2010). Ungulate embryos do not implant immediately upon arrival in the uterus and hatching from the zona pellucida; instead their trophectoderm expands dramatically changing the morphology of the conceptus from spherical to ovoid to tubular to filamentous (Fig. 2).

In embryos with a flat epiblast, extra-embryonic mesoderm cells have been identified that later contribute to chorion. The origin of this type of mesoderm has been debated since mesenchymal cells have been identified relatively early in development. It has been suggested that the extra-embryonic mesoderm cells delaminate from the early primitive streak, similar to what has been observed in the mouse. On the other hand, data from monkey embryos suggest that the extra-embryonic mesoderm cells differentiate before gastrulation from the reticulated primitive endoderm.

Gastrulation

The pluripotent epiblast is the source of most if not all fetal and adult lineages, both somatic and germline. In addition, extra-embryonic mesoderm is derived from the epiblast, as well as the ectodermal part of the amnion. Although these extra-embryonic tissues do not contribute to the fetus, they are crucial for survival of the fetus by providing protection and nutrition. Gastrulation

Fig. 2 Microphotographs of (A) a sectioned cup-shaped E6.5 mouse embryo; (B) E10 porcine embryo, dorsal view; (C) E10 porcine embryo lateral view (D) E14 horse embryo. *a*, anterior; *e*, epiblast; *m*, mesoderm; *p*, posterior; *ps*, primitive streak; *te*, trophectoderm; *ve*, visceral endoderm.

is a decisive moment in development as it transforms the epiblast from a single layer of similar cells into a multilayered embryo of which the different layers have made unidirectional choices. The process of gastrulation commences with coordinated growth of the epiblast and movement of epiblast cells towards the primitive streak followed by differentiation and ingression of mesendodermal cells. The internalized cells subsequently converge to the midline and extend along the antero-posterior axis upon undergoing an epithelial to mesenchymal transition and form the mesoderm and the definitive endoderm. The descendants of epiblast cells that do not pass through the primitive streak will constitute the ectodermal lineages (Lawson et al., 1991; Fig. 2).

Proteins belonging to the fibroblast growth factor (FGF) family have been identified as key regulators of the epithelial to mesenchymal transition during gastrulation. Already before a primitive streak is visually present in the mouse embryo, *Fgf8* is expressed in the presumptive dorsal part of the proximal epiblast. Mouse embryos genetically deficient for *Fgf8* besides a lack of FGF8 fail to express FGF4. As a result, mesodermal cells are formed but they fail to migrate away from the streak and instead accumulate at the proximal posterior side of the embryo. A similar clustering of cells at the posterior streak has been observed in embryos deficient for FGF receptor 1 indicating that indeed FGF signaling is crucial for partitioning of the germ layers at the primitive streak. FGF signaling induces the expression of the zinc finger transcription factor SNAIL. Cells that express high levels of SNAIL ingress through the streak while cells that express high levels of the X-linked *Sox3* gene maintain their position in the epiblast. SNAIL and SOX3 repress each other's transcription, thereby ensuring proper subdivision of the epiblast into definitive germ layers (Acloque et al., 2011). Cells of the epiblast have an epithelial character with apical-basal polarity and formation of a basal membrane. Ingression of cells through the primitive streak requires that these break the basal membrane and undergo an epithelial to mesenchymal transition. The formed mesenchymal cells lose cell polarity and cell-cell adhesion but gain migratory and invasive properties. This transition is independent of the differentiation to mesoderm or endoderm, as it has been demonstrated that mouse embryos genetically deficient of *Snail* still form mesoderm but the cells retain epithelial characteristics.

How do cells change from an epithelial sheet, the epiblast, to migratory mesenchymal cells? One important route for this transition is loss of the adhesion protein E-cadherin, a protein that is important for maintenance of adhesion junctions and epithelial tissue. By functioning as a transcriptional repressor, SNAIL can bind to the promoter of the gene coding for E-cadherin leading to a downregulation of E-cadherin expression. The epiblast cells lose their epithelial character and gain the mesenchymal phenotype required for gastrulation.

Fate Map

The developmental capacity of the rodent epiblast, after implantation and the formation of an egg cylinder and a pro-amniotic cavity, has been studied by grafting epiblasts under the kidney capsule of adult animals and analysis of the resulting teratomas. The explanted epiblast cells underwent an epithelial to mesenchymal transition as observed in cells migrating through the primitive

streak and could give rise to descendants of all three germ layers. Experiments by which epiblast cells were meticulously labeled, fragmented and subsequently grafted to other embryos indicated that although the cells are pluripotent, their progeny follows a determined developmental fate based on their position in the epiblast. Labeling individual epiblast cells of pre-streak and early primitive streak mouse embryos with horseradish peroxidase followed by *in vitro* culture revealed that epiblast cells differentiate and migrate in a reproducible and coordinate way. This enabled the construction of a detailed fate map of presumptive embryonic and extra-embryonic germ layers (Lawson et al., 1991). Cells of the lateral epiblast will primarily form embryonic mesoderm while cells from the proximal region will predominantly form extra-embryonic mesoderm and primordial germ cells. Definitive endoderm originates from a posterior region around the (future) streak.

Clonal analysis further revealed that the primordial germ cells also originate from but are not yet lineage restricted in the epiblast. Cells in the proximal epiblast are induced by BMP signals from the extra-embryonic ectoderm to form precursors of the primordial germ cells and allocation takes place during gastrulation in the mesoderm.

Clonal analysis also demonstrated that extensive cell mixing of epiblast cells occurred by morphogenetic movements and that descendants of single cells can contribute to different germ layers (Lawson et al., 1991). The observation that precursor cells for different lineages are present at specific regions of the embryo does not necessarily mean that these cells are irreversibly allocated or restricted in their developmental capacity. Indeed heterotopic explant experiments with pre- and early streak embryos demonstrated that it is the position of the cells, not the intrinsic characteristics of the cells that determines their fate (Tam and Zhou, 1996).

Epiblast Cell Flexibility

It has been demonstrated that, at least in the mouse, epiblast cells can transmigrate into the (primitive) visceral endoderm layer already before gastrulation. This is remarkable, since at this stage the epiblast and primitive endoderm are separated by a basement membrane. Exactly how cell change fate and migrate through the basement membrane is unknown (Hiramatsu et al., 2013). Whether epiblast transmigration to the visceral endoderm layer occurs specifically at the distal tip of the mouse egg cylinder remains unclear. Alternatively, it has become clear that in the mouse, primitive endoderm cells are not all displaced by differentiating epiblast cells that ingress through the primitive streak (Kwon et al., 2008). Rather than displacing and pushing the visceral endoderm cells proximally, the ingressing epiblast cells mix extensively with the visceral endoderm cells. As a result the gut tube, particularly the hindgut, is constituted by both visceral endoderm and epiblast-derived cells. Whether the flexibility of epiblast and primitive endoderm is unique to mouse embryos remains to be established.

Human Epiblast

Understanding human epiblast development beyond the blastocyst stage has been hampered by the invasive implantation into the uterus. Particularly the formation of the epiblast and the events associated with gastrulation has been a black box for the most part. The development of *in vitro* implantation models has allowed the *in vitro* transition from pre/to postimplantation development, although primitive streak formation and gastrulation has not been studied in these models due to ethical and legal restrictions (Shahbazi et al., 2016). Indeed *in vitro* culture of human embryos beyond 14 days or the beginning of primitive streak formation is not allowed in many countries. Questions that remain unresolved are the origin of the extraembryonic mesoderm, origin of the primordial germ cells and the flexibility of epiblast cells to contribute to hypoblast cells prior to primitive streak formation.

Levels of Pluripotency

The epiblast cells of preimplantation embryos, in the mouse between days 3.5 and 4.5 post-coitum, are by definition pluripotent since these cells can give rise to all somatic cell lineages and the germ cells. With the development of the embryo the pluripotency levels gradually diminish, which can be observed for instance by the chromatin state of the cells and the gene expression profile. Shortly after implantation, the pluripotency levels of mouse epiblast cells subside and after gastrulation and accompanying terminal germ layer choice the cells have lost their pluripotent character. In developing embryos, the pluripotency state is very transient as the function of the epiblast is to form a fetus. The pluripotency levels of pre- and post-implantation epiblast cells has been “captured” by *in vitro* culture, and under the right conditions the cells can maintain their pluripotency levels as embryonic stem (ES) cells and epiblast stem cells (EpiSCs) respectively. The pluripotency level of preimplantation epiblast and ES cells is considered to be unrestricted and is therefore referred to as “naïve” while that of post-implantation epiblast and EpiSCs are already “primed” for lineage commitment. Interestingly, human ES cells share more characteristics with mouse EpiSCs and are therefore also considered to be at a primed state of pluripotency. Indeed naïve ES cells form tightly adhering dome-shaped aggregates reminiscent of the blastocyst stage epiblast, while EpiSCs form flat colonies similar to the epithelialized post-implantation epiblast. Naïve pluripotent cells are characterized by high levels of OCT4, NANOG and KLF. Other indications of an open chromatin state and active transcription are large regions of hypomethylated DNA, permissive H3K4 trimethylation and in female cells two active X-chromosomes. Conversely primed epiblast cells, including EpiSCs, also express high levels of OCT4 and NANOG, but low levels of KLF4, and start to express

BRACHYURY, SOX17 and GATA4/6. In addition the EpiSCs display higher DNA methylation levels, and repressive H3K27 trimethylation. In contrast to the naïve state, in female primed epiblast cells one of the X-chromosomes is inactivated. ES and EpiSCs have revealed that alternate enhancer usage dictates the pluripotency character of these cells and it can be assumed that similar differences in enhancer activity states are present in pre- and post-implantation epiblast cells.

During development, the naïve and primed pluripotency states of the epiblast are very transient. However, when the environmental conditions are suboptimal for pregnancy, embryos can arrest in development before implantation, a state known as diapause or delayed implantation. It is thought that in this diapause state the naïve pluripotent epiblast cells self-renew, very much similar to the behavior of ES cells.

Conclusion

The epiblast is the pluripotent primary lineage that will form the definitive germ layers in a complex process of differentiation and morphogenetic movements called gastrulation. After gastrulation the developmental capacity of the differentiating cells is restricted to the residing germ layer. Most of what we know about epiblast development comes from mouse data. However, the mouse epiblast is uniquely cup-shaped, opposed to the planar morphology of the epiblast of most mammalian species. Studies with pluripotent stem cells and in vitro cultured embryos may in the future contribute to our knowledge of the epiblast.

Glossary

Chromatin DNA packaged by proteins. This is the way DNA molecules, which are much longer than the cell, that fit into the nucleus.

Histone A family of basic proteins that bind to DNA in eukaryotic cells to form chromatin.

Nucleosome The basic unit of somatic cell chromatin structure. One nucleosome contains a tetramer of H3 and H4 histones and two dimers of H2A and H2B histones, and about 147 bp of DNA coiled 1.7 time around the histone octamer.

Protamine Very basic proteins that fold DNA into chromatin only in sperm cells.

Spermatids Precursor haploid cells that differentiate into spermatozoa.

Spermatozoa The male gamete. It is the final, mature form of the sperm cell that carries the father's DNA to the oocyte.

Spermiogenesis The process of the differentiation of spermatids to spermatozoa.

Introduction

During spermiogenesis, the haploid round spermatid differentiates into a markedly different spermatozoon, with a very long tail and a much more condensed nucleus. During this process, the paternal genome has two functions. It must produce the proteins necessary to complete the changes as the chromatin shuts down all transcription, and it must repackage itself into a much more condensed form. As discussed later, the first task is accomplished by the production of several mRNAs that are stored and not translated until they are needed. The second task, however, is much more complicated, and will take up the majority of this article.

Chromatin Changes During Spermiogenesis

Delayed Translation

The round spermatid is the first haploid cell produced during spermatogenesis. This is the cell that has the correct number of chromosomes (half of the normal) to fertilize an egg initiating the process of embryogenesis. Its chromatin is, as far as we can tell, relatively normal, bound by histones into nucleosomes with DNA that is accessible to transcription factors (Fig. 1A). During spermiogenesis, the histones are gradually replaced with protamines (see below), greatly reducing the access to the DNA by other proteins to almost zero (Fig. 1C). However, there are proteins that are required to complete the differentiation of the round spermatid to the spermatozoon after transcription has shut down. To solve this problem, the round spermatid produces several mRNAs that will be used later in spermiogenesis, and sequesters them with the translational repressor, Y-box protein (YBX2) (Kleene, 2016, Yang et al., 2005). At later stages during spermiogenesis, the YBX2 repression is removed, and the mRNAs are translated into the proteins that are required.

Crystallizing the Sperm Genome

During the later stages of spermiogenesis, the chromatin is condensed into an almost crystalline like state (Fig. 1C). This is to protect the paternal genome during its transit to the egg at fertilization. To understand the complexity of how the sperm chromatin is condensed during this process, it is helpful to consider a few of the topological problems that must be overcome. In the round spermatid, about 1 m of DNA, divided into 23 different chromosomes (in the human) is coiled by histone octamers into roughly 15 million nucleosomes, in which the DNA is wrapped twice around a core of histones (Fig. 1A). These very long, but very thin strands of DNA are coiled into a nucleus that is about 10 μm in diameter. To repackage this DNA in sperm, most of these 15 million nucleosomes must be unwound, then bound to another group of proteins called protamines that form large toroids with much less coiling (Fig. 1). All this must be done sequentially and in situ—the DNA cannot be unwound completely or it would no longer fit into the nucleus. Thus, the condensation of DNA during spermiogenesis is a highly coordinated event that requires precise timing and spatial organization. Many years ago two proteins, called transition proteins (TP) were identified that were important to help the sperm make this crucial change in DNA packaging. Both are small, basic proteins that are only synthesized during late spermiogenesis. Until recently (see below) it was not known exactly how the TPs functioned to assist in the replacement of histones by protamines (PRMs).

Fig. 1 Schematic representation of how sperm packaging changes during spermiogenesis. (A) Packaging of DNA by nucleosomes into a solenoid-loop. This represents roughly 50,000 bp of DNA. (B) The DNA if all the histones were removed, and the supercoils relaxed by a factor of 6. (C) The same DNA organized into a protamine toroid. This figure is based on a similar in figure (Sotolongo et al., 2003)

Reorganizing the Sperm Chromatin

Spermatid Chromatin at the Time of Histone-to-Protamine Transition: Open Questions

The original model for the function of TPs was that they would completely replace the histones, and then would themselves in turn be replaced by protamines in two sequential complete reorganizations of the future sperm DNA. However, the breakthrough observation by Meistrich laboratory that histones could be replaced in the total absence of TPs (Shirley et al., 2004, Zhao et al., 2004b, Zhao et al., 2004a) prompted the investigators to rethink the function of TPs in histone removal and to question the functional interplay between histones, TPs and PRMs (Barral et al., 2017). Indeed, Meistrich laboratory data suggested that TPs are only necessary for the processing of Pre-PRM2 and the PRM-dependent final tight packaging of the male genome (Shirley et al., 2004, Zhao et al., 2004a). The disappearance of histones under these conditions clearly indicates that PRMs are sufficient to replace histones and hence raised the question of the precise function and utility of TPs in the process of histone removal. Additionally, large-scale histone hyperacetylation and synthesis of specific histone variants are known to accompany histone removal and the subsequent structural transitions. These events are also expected to play a role in driving the genome reorganizations that take place in spermatids (Govin et al., 2004, 2007; Goudarzi et al., 2014).

The full picture of the mechanisms underlying histone-to-protamine transition should therefore integrate a functional interplay between histones, histone variants, histone hyperacetylation, TPs and PRMs. The burning question is therefore how these events act together and how their action is coordinated to drive the genome scale nucleohistone-to-nucleoprotamine transition.

Histone Variant-Directed Histone-to-PRM Transition

In an attempt to identify histone variant candidates involved in a specific organization of chromatin that could facilitate histone eviction, a proteomic approach was set up for an unbiased identification of histones in fractionated spermatogenic cells, which led to the discovery of a series of new histone variants of the H2A and H2B types (Govin et al., 2007). A detailed analysis of the expression of these histone variants pointed to a specific member that accumulated during late spermatogenesis at the same time and in the same cell types as TPs (Govin et al., 2007, Barral et al., 2017). This histone variant of the H2A type, named H2A.L2 (Talbert et al., 2012, El Kennani et al., 2017), belongs to a specific category of histone H2As that are shorter than the canonical histone H2As and lack a region present at the C-terminal part of most of H2A members (Syed et al., 2009, Bao et al., 2004). This region has a critical structural role within a nucleosome as well as in the structure of chromatin fiber. In canonical

H2As, the C-terminal region bears a docking domain that mediates the interaction of H2A with H3–H4 dimers and is essential for the stabilization of the H2A–H2B dimer in the nucleosome (Luger et al., 1997). Additionally, H2A.L.2 also presents significant alterations in an acidic patch, normally present in canonical H2As, which plays an important role in stabilizing nucleosomes–nucleosome interactions (Zhou et al., 2007, Soboleva et al., 2011). Altogether these structural characteristics indicate that nucleosomes bearing H2A.L.2 should present specific features that drastically differentiate these nucleosomes from canonical ones.

In vitro reconstitution assays using purified histones revealed that H2A.L.2-containing nucleosomes indeed possess particular properties that strongly support a specific role for this histone in “preparing” the nucleosomes for histone replacement. H2A.L.2 nucleosomes present flexible DNA ends due to the release of nucleosomal DNA at the entry and exit of nucleosomes and hence, in contrast to canonical nucleosomes, protects only around 120–130 base-pair of DNA against micrococcal nuclease (MNase) digestion (Barral et al., 2017). H2A.L.2’s major function could therefore be related to its ability to create a relaxed chromatin fiber with “open” nucleosomes.

Indeed, our knowledge of another histone variant that also “opens” the nucleosome, the centromeric H3 variant, CENP-A, helps to better understand the function of H2A.L.2. CENP-A’s ability to “open” the nucleosome and release flexible DNA ends is required to load chromatin with the inner kinetochore plate proteins (Roulland et al., 2016). Interestingly, the incorporation of H2A.L.2 into a nucleosome has almost the same structural consequences as the incorporation of CENP-A, and similarly provides a nucleosomal platform for the loading of non-histone proteins. In vitro reconstitution experiments show that, in fact, H2A.L.2 nucleosomes, in contrast to canonical nucleosomes, could load TPs.

A series of in vivo experiments strongly supported the conclusions of these in vitro assays. Indeed, in the absence of H2A.L.2, defective TP incorporation to chromatin was observed and large amounts of TP2-Pre-PRM2 could be immunopurified from elongating spermatids nuclear extracts. These observations indicated first that, in the absence of H2A.L.2, nucleosomes resist invasion by TPs and second that the non-incorporated accumulating TPs trap the incoming Pre-PRM2 and hinders its further processing. From these observations it could be concluded that H2A.L.2 incorporation into nucleosome relaxes chromatin and individually opens all the nucleosomes that become exposed to TPs. The loaded TPs in turn buffer and guide the assembly of PRMs (Fig. 2).

In the absence of H2A.L.2, as observed in the absence of TPs, PRMs can displace histones but the Pre-PRM2 processing and the final compaction of the genome are defective. These observations suggest that TPs’ primary function is not to displace histones but to guide the action of PRMs. These data also invite us to revisit the common belief that histones are first replaced by TPs and that PRMs then replace TPs. In fact, the in vitro reconstitution assays show that while, H2A.L.2 nucleosomes could load TPs, no DNA

Fig. 2 A new model for the role of histone variants and transition proteins in replacing histones with protamines. See text for details.

release was observed following the incubation of either canonical or H2A.L.2 nucleosomes with increasing amounts of TPs (Barral et al., 2017).

It is of note that, at the time of H2A.L.2 synthesis, the major chromatin H2B species is TH2B (Montellier et al., 2013), which preferentially dimerizes with H2A.L.2 (Govin et al., 2007). It is also known that, compared to the canonical H2Bs, TH2B itself could contribute to some extent to the generation of less stable nucleosomes (Shinagawa et al., 2014, Montellier et al., 2013). In the light of these investigations altogether a new vision of histone-to-protamine transition should be considered, where nucleosomes are first prepared for histone eviction by incorporation of a H2A histone variant which relaxes the chromatin fiber and opens nucleosomes hence mediating the loading of non-histone TPs, whose major role is to buffer the action of the PRMs which are the true displacers of histones (Fig. 2).

Histone Hyperacetylation and Histone Removal

Since the early 1970s different investigators reported the occurrence of histone hyperacetylation in spermatogenic cells from various species, more specifically those undergoing a histone-to-protamine transition during their spermatogenesis (Govin et al., 2004). A detailed study of the timing of histone acetylation during mouse and human spermatogenesis highlighted the occurrence of histone hyperacetylation precisely in the elongating spermatids associated with histone removal (Hazzouri et al., 2000, Faure et al., 2003).

Based on the hypothesis that histone acetylation could signal histone removal through a bromodomain containing protein, the bromodomain testis-specific protein Brdt was characterized as a potentially promising factor, capable of reorganizing hyperacetylated chromatin (Pivot-Pajot et al., 2003). Brdt is a protein containing two tandem bromodomains, uniquely expressed in testis, from spermatocytes all through spermatogenesis (Gaucher et al., 2012). Structural and in vivo studies showed that Brdt's first bromodomain (BD1) specifically recognizes hyperacetylated H4 (Sasaki et al., 2009, Moriniere et al., 2009). Using a mouse model expressing a Brdt deleted of its first bromodomain, the involvement of BD1 in the removal of histones could be demonstrated (Gaucher et al., 2012). Finally, a recent investigation showed that Brdt BD1 is unable to recognize butyrylated histone H4 tails and that, according to the proposed role of Brdt in removing acetylated histones, histone H4 butyrylated at K5 and K8 escapes the wave of acetylation-dependent histone removal (Goudarzi et al., 2016). Despite these accumulating data on the role of Brdt, specifically of its BD1 in histone removal, additional investigations are required to define how Brdt's interaction with hyperacetylated histone H4 mediates histones removal.

Additional recent reports also support a molecular link between histone acetylation and histone removal by proposing a role for the histone acetyltransferases MOF (Lu et al., 2010) and TIP60 (Dong et al., 2017) in histone hyperacetylation and removal, and the action of the H2A ubiquitin ligase RNF8 is histone ubiquitination and degradation (Lu et al., 2010, Gou et al., 2017). The most direct evidence for a role of histone hyperacetylation in their degradation in elongating spermatids comes from the suggested ability of the testis-specific proteasome associated with PA200 to directly bind and degrade acetylated histones in spermatogenic cells (Qian et al., 2013). However, some of these data are controversial, since the role of RNF8 in histone degradation could be questioned. Indeed no effect on histone-to-protamine replacement was observed in RNF8 KO spermatogenic cells (Sin et al., 2012) and, in PA200 KO spermatids, histones are finally removed, although probably with a delay (Qian et al., 2013).

The challenge is now to precisely identify the mechanisms linking histone hyperacetylation to histone eviction, and to discover the molecular link between these histone acetylation-dependent and H2A.L.2-dependent mechanisms.

Conclusion

Recent data has shed much light on the complex mechanisms by which spermatids condense their DNA into the highly compact chromatin of mature spermatozoa. The new model suggests that specific histone variants first open the nucleosomes and transition proteins bring the pre-protamines to the nucleosomes to replace the histones. This coordinated process allows for the orderly transition of the entire paternal genome to a compact, protected state so that the DNA is protected during the transit in fertilization.

Glossary

Embryonic stem cells They are derived from the inner cell mass cells of the blastocyst with pluripotency to give rise to tissues of all three germ layers when induced to differentiate.

Embryonic tissue It is derived from the epiblast that contributes to all three germ layers of the embryo giving rise to all the tissues of the fetus.

Extraembryonic tissue It is derived from the trophoctoderm and primitive endoderm of the blastocyst, giving rise to the placenta and part of the extraembryonic membranes surrounding the fetus.

Heterochromatinization It is a process to form heterochromatin, which is originally identified as an electron-dense entity in the nucleus. It is highly condensed and transcriptionally inactive chromatin. An inactive X chromosome is referred to as facultative heterochromatin, which can take euchromatic as well as heterochromatic state depending on the developmental stage and cell-type.

Histone tail An N-terminal amino acid stretch of core histones, which protrudes from a nucleosome and is subjected to various chemical modifications at the specific residues. Such modifications have various impacts on transcriptional state through changes in the chromatin structure.

Yeast artificial chromosome (YAC) It is a functional artificial chromosome containing a centromere sequence, telomere sequences, and a replication origin, which allow it to replicate autonomously and propagate from one cell to its daughter cells, in combination with a couple of selectable markers. A YAC can take a long DNA fragment such as partially digested mouse genomic DNA up to 1 Mb and allows to generate an unlimited number of copies of YAC containing a particular long DNA sequence by introduction into yeast cells.

Introduction

Female mammals have two X chromosomes (XX) and males have one X and one Y chromosome (XY). An X chromosome carries more than 1000 genes including those essential for embryo development, while a Y chromosome contains tens of genes required for only male determination and development. One can expect that such a big difference in the number of X-linked genes between the sexes, if many of them are fully expressed, would result in huge imbalance. To avoid such chaotic situation, female mammals have evolved a mechanism to inactivate one of the two X chromosomes during early development ([Lyon, 1961](#)). It is called X-chromosome inactivation (X-inactivation). Once X-inactivation occurs, the inactivated state of the chromosome is stably transmitted to daughter cells through successive cell divisions. Therefore, this phenomenon has been drawing much attention of researchers as one of epigenetic gene regulations for more than half a century. This article will focus on the X-inactivation mainly in mice, which have been most extensively studied as a model animal and made a significant contribution to our knowledge about this unique epigenetic mechanism.

X-Inactivation in Mice

A single fertilized egg of mammals forms two different types of tissues, embryonic and extraembryonic tissues. The former gives rise to all the tissues of the embryo proper, whereas the latter contributes to the remaining extraembryonic components, such as the yolk sac and placenta. Interestingly, the X-inactivation pattern is different between these two tissues in mice and most probably other rodents ([Fig. 1](#)).

Imprinted X-Inactivation

Each of the X chromosomes derived from an egg and sperm is initially active in the zygote, but one of them becomes transcriptionally inactivated at around the 4- to 8-cell stages in favor of the paternal X chromosome ([Okamoto et al., 2004](#)). This is, therefore, called imprinted X-inactivation. Following cleavage, a fertilized egg develops to a blastocyst, which consists of the trophoctoderm forming the outer layer of the embryo and undifferentiated inner cell mass (ICM) cells inside. A part of the ICM cells subsequently differentiates into the primitive endoderm at around the time of implantation. The trophoctoderm and primitive endoderm will contribute to the extraembryonic tissues, in which the paternal X chromosome inactivated early on stays repressed. It should be noted, however, that there is little evidence of imprinted X-inactivation in the extraembryonic tissues of eutherian mammals except

Fig. 1 Changes in the activity of X chromosomes during mouse development. Modified from SadoT: Imaging property.

for rodents. Interestingly, marsupials, which diverged 130 million years ago from the ancestor of therian, show imprinted X-inactivation in not only the extraembryonic but also the embryonic tissue.

Random X-Inactivation

Paternal X chromosome inactivated at the early preimplantation stage transiently restores its transcriptional activity in those cells that have contributed to the ICM cells (Mak et al., 2004). This reactivation is considered to be a part of reprogramming, which cancels the developmental program of the extraembryonic tissues and allows to initiate another developmental program for the embryonic tissue that differentiates into various types of cells of the fetus including germ cells. The ICM cells subsequently form epiblast soon after implantation, which is still undifferentiated pluripotent cell population, and either the maternal or paternal X chromosome undergoes inactivation in a random fashion as cells differentiate (Monk and Harper, 1979). This is referred to as random X-inactivation. It is considered that X-inactivation completes by gastrulation and the inactive state of the X chromosome once established is stably maintained throughout embryogenesis and the life of individual after birth. Mouse embryonic stem (ES) cells, which are derived from the ICM cells and retain pluripotency to differentiate into every cell type of the fetus, have been used for the studies of random X-inactivation as they recapitulate essentially the whole process of random X-inactivation in culture. While female ES cells retains two active X chromosomes in undifferentiated state, one of them undergoes inactivation in a random fashion upon induction of differentiation.

X-Reactivation

It is known that there are two distinct phases when the inactivated X chromosome becomes reactivated during embryonic development. As mentioned earlier, reactivation occurs in the ICM cells of the preimplantation blastocyst for epigenetic reprogramming. Another reactivation of the inactive X chromosome occurs in the primordial germ cells (PGCs), which are the progenitors of future oocytes (Monk and McLaren, 1981). PGCs emerge in a small subset of the somatic cell population of the postimplantation embryo by receiving extrinsic signals from the surrounding somatic cells at around the time of gastrulation. These signals trigger expression of PGC-specific genes. This process also requires reprogramming of the epigenetic state of the somatic cell-lineage to the germ cell-lineage. The X chromosome that has been inactivated early on appears to gradually reactivate in PGCs during their journey from the site they emerge to the genital ridges, the future ovaries. The reactivated X chromosome stays active during the rest of oogenesis until the maternal X chromosome is chosen during random X-inactivation in the embryonic tissues of female offspring.

X-reactivation also occurs in somatic cell nuclear transfer (SCNT) embryos (Eggan et al., 2000). The inactive X chromosome in the donor somatic cell becomes reactivated when exposed to the egg cytoplasm. Similar reactivation is also observed when induced

pluripotent stem (iPS) cells are generated following transduction of the Yamanaka four factors (Oct4, Sox2, Klf4, and c-Myc) in female mouse somatic cells (Maherali et al., 2007). Although the molecular mechanisms of X-reactivation in SCNT embryos and iPS cells as well as in the ICM cells and PGCs in vivo are largely obscure, given the fact that the inactive X chromosome always becomes reactivated when the genome is reprogrammed, it is likely that X chromosome reactivation is one of the most important processes in the genome reprogramming.

XIST/Xist

The X-inactivation center (Xic) has been identified on an X chromosome by classic cytogenetic analysis as a region essential for X-inactivation to occur in cis (Rastan, 1983). In the early 90's, X inactive-specific transcript (*XIST*) RNA was serendipitously found in human as a 17-kb long noncoding RNA exclusively expressed from an inactive X chromosome (Brown et al., 1991). Subsequent cloning of a mouse homolog, *Xist*, accelerated the analysis of the molecular mechanisms of X-inactivation (Borsani et al., 1991; Brockdorff et al., 1991). *Xist* RNA, although, transcribed by RNA polymerase II, and subjected to splicing and polyadenylation as is the case of common protein-coding RNA, it escapes nuclear export and stays in the nucleus to accumulate on the inactive X chromosome it originates from. Extensive studies using mouse ES cells revealed that while the both *Xist* alleles are expressed at a very low basal level in undifferentiated ES cells, one of them is upregulated on the X chromosome to be inactivated upon differentiation and its transcripts spread along the chromosome in cis. It has been suggested that *Xist* RNA thus accumulated on the X chromosome recruits proteins involved in gene silencing and induces chromosome-wide heterochromatinization (Fig. 2). Targeted disruption of *Xist* in ES cells and mice clearly demonstrated that *Xist* is essential for X-inactivation to occur in cis, and therefore, the X chromosome deficient for *Xist* never undergoes inactivation (Penny et al., 1996; Marahrens et al., 1997). It has been shown that yeast artificial chromosome (YAC) containing the *Xist* gene and surrounding region integrated to an autosome as a transgene apparently acts as Xic. *Xist* RNA expressed at the ectopic locus spreads along the chromosome and induces silencing of, at least, some autosomal genes. These results suggest that *Xist* is responsible for the most part of the function of Xic. Comparison of human and mouse *XIST/Xist* RNA sequences revealed the presence of some highly conserved repeated sequences, termed the A-E repeats. Another repeat, termed the F-repeat, was also found as a conserved repeat among mouse subspecies (Fig. 3). Of these conserved repeats, the A-repeat, which is predicted to form a stem-loop structure, has been shown to be indispensable for the proper silencing function of *Xist* RNA in differentiating ES cells and mice (Wutz et al., 2002; Sakata et al., 2017). In addition, since the mutated *Xist* allele lacking the genomic sequence corresponding to the A-repeat fails to be upregulated, it is likely that the A-repeat sequence is also essential as a cis-element for transcriptional regulation of *Xist* (Hoki et al., 2009).

It is known that an antisense RNA is transcribed at the *Xist* locus, which is referred to as *Tsix* (Lee et al., 1999) (Fig. 3). While *Tsix* and *Xist* are expressed on both X chromosomes in undifferentiated female ES cells, *Tsix* becomes downregulated on one X chromosome and then, in turn, *Xist* comes to be upregulated on the same X chromosome and coats it to induce X-inactivation. In contrast, *Tsix* expression on the other X chromosome persists for a while and then both *Tsix* and *Xist* becomes downregulated to leave the X chromosome being active. Therefore, *Tsix* is a negative regulator of *Xist*, which prevents upregulation of *Xist* at the onset of X-inactivation (Sado et al., 2001). Available evidence suggests that *Tsix* is involved in the establishment of the repressive epigenetic modifications at around the *Xist* promoter.

Epigenetic Modifications

Epigenetic regulation is a mechanism that controls gene expression via DNA methylation and histone modifications such as acetylation, methylation, and ubiquitination at the N-terminus region, so called histone tail. The inactive X chromosome is characterized by various repressive epigenetic modifications (Fig. 2). Substantial part of DNA methylation occurs at CpG (cytosine-phosphodiester bond-guanine) dinucleotide sequences in the mammalian genome. Classically, it is well known that CpG islands, which are enriched with CpG dinucleotide sequences and often found in the regulatory region of genomic DNA such as the promoters and enhancers, are highly methylated on the inactive X chromosome as compared to those on the active X chromosome. DNA methylation is, however, thought to play a role in the maintenance of X-inactivated state but is dispensable for the initiation of X-inactivation. It has been suggested that de novo DNA methylation of the inactive X chromosome is mediated by de novo DNA methyltransferase Dnmt3b.

While the inactive X chromosome is devoid of histone modifications for active chromatin such as dimethylation of histone H3 at lysine 4 (H3K4me2) as well as acetylation of histone H3 and H4, it is enriched with trimethylation of histone H3 at lysine 27 (H3K27me3), di- and trimethylation of histone H3 at lysine 9 (H3K9me2/3), monomethylation of histone H4 at lysine 20 (H4K20me1), and monoubiquitination of histone H2A at lysine 119 (H2AK119ub1). It has been considered that *Xist* RNA accumulated on the X chromosome recruits polycomb repressive complex 2 (PRC2) whose catalytic core, Ezh2 histone methyltransferase, in combination with Suz12 and Eed mediates H3K27me3. Subsequently, another polycomb repressive complex, PRC1, recognizes H3K27me3 and its E3 ubiquitin ligase activity mediated by Ring1a/b facilitates H2AK119ub1. More recent study using genetics, however, demonstrated that H2AK119ub1 occurs on the X chromosome in the absence of H3K27me3 but not the other way around, therefore, no H3K27me3 on X without H2AK119ub1. It is still unknown, however, how H2AK119ub1 recruits PRC2 on the inactive X chromosome and exerts its effect on heterochromatinization and X-inactivation. Further studies are necessary for elucidating how histone modification patterns are established on the inactive X chromosome and how *Xist* RNA is involved in these processes.

Evolutionary Aspects of X-Inactivation

As mentioned earlier, X-inactivation is also observed in marsupials, but in contrast to eutherians, the paternal X chromosome is always inactivated in every somatic cell like that in the extraembryonic tissues of the mouse. Other differences between eutherian and marsupials include the stability of X-inactivated state and the levels of DNA methylation. It is known in marsupials that spontaneous reactivation of the inactive X chromosome often occurs and differential methylation of the CpG islands between an active and an inactive X chromosome is not prominent. The lack of DNA methylation may partly account for less stable X-inactivation in marsupials. Furthermore, the *Xist* gene is not found in the marsupial genomes. Comparison of the synteny at the Xic region among many different species suggests that the eutherians *Xist* gene has evolved from a protein-coding gene, *LnX3*, which is present up to marsupials. This indicates that marsupials inactivate an X chromosome without *Xist*. Afterwards, a novel noncoding RNA acting like *Xist* RNA was found in marsupials. It is exclusively expressed from and coats the inactive paternal X chromosome in female opossum, and therefore, named *Rsx* (RNA on the silent X) RNA (Grant et al., 2012). *Rsx* RNA is as long as 27-kb in length and subjected to processing such as polyadenylation and splicing like *Xist* RNA. *Rsx* RNA expressed on an autosome in mouse ES cells coats the chromosome, to which the transgene has been integrated, and induces silencing of, at least, three genes nearby the integration site of the transgene. The many characteristic features of *Xist* RNA are shared by *Rsx* RNA, but there is no sequence homology

between them. It is most likely that eutherians and marsupials have evolved noncoding *Xist* and *Rsx* RNA, respectively, as a result of convergent evolution to compensate for the dosage difference of X-linked gene between the sexes by X-inactivation.

Glossary

Axoneme The central strand of a cilium or flagellum. It is composed of an array of microtubules; typically in nine pairs around two single central ones.

Active stroke The propulsive movement of cilia beating, it involves the entire cilia. Different from basal stroke, which starts from the basal root and propagates like a wave throughout cilia.

Apical membrane The plasma membrane faces to the lumen in a polarized cell.

Basal foot Is an extension of cytoplasmic process from the microtubule-organizing center at the base of the cilia. It determines the direction of cilia beating.

Cilium A hair like organelle that extends outside of the cell.

Ectopic pregnancy A medical condition when an embryo is implanted outside of the uterine cavity. The most common site for this to occur is inside the Fallopian tube.

Estrogen A major sex steroid hormone produced primarily by ovaries. It is responsible for reproductive development.

Progesterone A major sex steroid hormone produced primarily by ovaries. It is responsible for inducing physiological changes to maintain a successful pregnancy.

Prostaglandins Small lipids that are found in most animal tissues and play many physiological roles.

Transudation Passage of the fluid through cell membrane as a result of osmotic pressure.

Transgenic mice Genetically engineered mice used to study genetic functions.

Introduction

The oviduct (or the Fallopian tube in humans) is a trumpet-like structure, that connects the ovary and the uterus, and is the sole site of embryo transport. Embryo transport is the process by which an embryo travels from the site of fertilization, in the ampulla of the oviduct, to the implantation site in the uterus. In humans, embryo transport is difficult to study because it occurs during the first four days of pregnancy before women even know they are pregnant. A large majority of the information known about embryo transport in humans is inferred from studies in animals. Historically, embryo transport is thought to be a passive process, in which the oviduct's role is little more than a path for the embryo to follow. Over the years it has become more and more apparent that embryo transport is much more complex than initially assumed.

It is proposed that a variety of factors can affect embryo transport, including oviductal muscle contractions, ciliary activities, and fluid secretions. All of these mechanisms work together to increase, decrease, or halt the embryos movement, ensuring the delivery of the embryo into the uterus at precisely the right time for successful implantation. Variations in any of these processes can lead to the embryo arriving in the uterus at the wrong time, resulting in an unsuccessful pregnancy.

The amount of time the embryo spends in the oviduct varies between species. For example, human embryos spend approximately 80 h in the Fallopian tube (Croxatto, 2002). In rodents, the embryo travels swiftly through the ampulla to the isthmus where migration slows, and the embryo stays in the isthmus for about 3 days. Pig embryos spend 1–3 days (Oxenreider and Day, 1965), cow embryos 2–4 days (Crisman et al., 1980), sheep embryos 2–3 days, and horse embryos spend 5–6 days in the oviduct (Betteridge et al., 1982). For other species, refer to a comprehensive review by Croxatto (2002). The mechanisms for moving embryos into the uterus are considered to be a combination of oviduct ciliary activity, oviductal fluid flow, and waves of muscle contraction and relaxation all mainly orchestrated by the sex steroid hormones, estrogen (E_2) and progesterone (P_4) (reviewed in Li and Winuthayanon, 2017).

Factors Affecting Embryo Transport

Role of Sex Steroid Hormones During Embryo Transport

E_2 and P_4 play an essential role in regulating many physiological functions of our body. E_2 and P_4 initiate the signaling transduction pathway through their receptors, altering downstream gene expression, and modulating cellular behavior to change the speed of embryo transport. Specifically, three main factors regulating embryo transport are controlled by E_2 and P_4 : (1) muscle contraction, (2) the beat frequency of ciliated cells, and (3) the fluid volume in the tubal lumen. E_2 induces these factors to accelerate the embryo transport. In most circumstances, P_4 opposes E_2 action by suppressing E_2 signaling pathways; hence balancing E_2 activity (Fig. 1). Later sections will explain detailed mechanisms based on the three components of embryo transport.

Fig. 1 An illustration of the action of E_2 and P_4 on embryo transport. E_2 increases muscle contractility, CBF, and oviductal fluid volume while P_4 opposes E_2 's action. The pathways regulating muscle relaxation through P_4 still remain unclear. Human Fallopian tube obtained from Dr. Ken-Ichi Takemaru (Stony Brook University, School of Medicine) with institutional ethics approval.

Muscle contractions

Fertilization occurs in the ampullary region of the oviduct. Two smooth muscle layers surround the ampulla and isthmus: an inner circular and the outer longitudinal layers. The contractility of these smooth muscle layers oscillates over the course of the ovarian cycle. In many species, female sex steroid hormones regulate muscle contraction in the oviduct, but there is still speculation as to whether oviductal muscle contractility plays a role in embryo transport. For example, inhibition of muscle activity in the ampullary region of rats and rabbits via a β -adrenergic agonist does not affect egg transport (Halbert et al., 1976, 1989).

As for hormonal regulation of muscle contractility, E_2 increases muscle contraction while P_4 suppresses it (Lindblom et al., 1980; Helm et al., 1982). When circulating level of E_2 peaks, luteinizing hormone (LH) is released. In pigs, E_2 promotes the expression of LH receptor on the smooth muscle and induces oviductal muscle relaxation (Gawronska et al., 1999). In addition, E_2 increases the expression of prostanoid receptors (EP2, EP4, and FP) in the bovine oviductal smooth muscle (Huang et al., 2015). When activated by prostaglandins (PGs), EP2 and FP have a contractile effect while EP4 has a relaxing effect. In humans, PGE_2 and $PGF_{2\alpha}$ are present in the circular and longitudinal smooth muscle of the Fallopian tube (Lindblom et al., 1978). Treatment with PGE_2 and $PGF_{2\alpha}$ induces an increase in the muscle contraction of the human Fallopian tube (Wanggren et al., 2006, 2008). In summary, it appears that the action of E_2 on oviductal smooth muscle contraction is due to the signaling activated by PGs.

P_4 signaling suppresses E_2 -induced oviductal smooth muscle contraction, but the exact mechanism remains unclear. In cow and mouse oviduct, progesterone receptor (PGR) is present in both epithelial and smooth muscle cells (Valle et al., 2007; Ismail et al., 2002). Contraction of smooth muscle in the colon is inhibited through P_4 -mediated increased intracellular cAMP level (Cheng et al., 2010), therefore, it is possible that a similar mechanism of smooth muscle contraction may apply in the oviduct.

Non-hormonal signaling pathways in the oviduct influencing muscle contraction include endothelin, prostaglandin-endoperoxide synthase 2 (PTGS2, also known as COX2), hydrogen sulfate, and cannabinoid receptor signaling pathways.

Endothelin is a short amino-acid peptide that directly affects embryo transport by increasing muscle contractility (Shihoya et al., 2016; Kobayashi et al., 2016). In rats and cows, endothelin receptor A (ET_A) is expressed in the isthmus region of the oviduct epithelial cells (Rosselli et al., 1994; Al-Alem et al., 2007). Its role in the ovary and oviduct is reviewed by Bridges et al. (2011).

E_2 is also shown to increase expression of COX2, an enzyme responsible for catalysis of prostaglandin precursor proteins. In rats, treatment with E_2 stimulates the secretion of COX2 into the lumen of the oviduct (Perez Martinez et al., 2006). In cows, COX2 is expressed at the highest level during the follicular and postovulatory phases. This intermediate enzyme indirectly regulates tubal muscle contraction impacting embryo transport (Oda et al., 2006).

Hydrogen sulfate (H_2S) is a significant vasodilator and smooth muscle relaxant in mammals. In humans, H_2S relaxes the spontaneous muscle contraction of the oviduct. Dysregulation of H_2S leads to a delay in embryo transport and development (Ning et al., 2014).

Cannabinoid signaling is also involved in muscle contractility and is proposed as a pathway that prevents prolonged embryo retention in the oviduct. Genetic knockout mice, as well as chemical inhibition, of the cannabinoid receptors resulted in unsuccessful implantation due to an embryo transport defect (Wang et al., 2004).

In addition to facilitating the embryo transport, muscle contraction at junctions of the oviduct can also detain underdeveloped embryos. Human embryos spend majority of their time in the ampulla region of the Fallopian tube and retain at the ampullary-isthmic junction (AIJ) region for couple days, followed by a quick progression through the isthmus (Croatto, 2002).

The last stop for the embryo before entering the uterus is the utero-tubal junction (UTJ). Inflammation or anatomical defects of this junction caused by a mutation in the *Dicer* gene can lead to a transport failure (Nagaraja et al., 2008; Gonzalez and Behringer, 2009). However, in rabbits, removal of the AIJ and the UTJ did not change implantation rate (Eddy et al., 1977; Perez et al., 1981), indicating that embryo transport is not affected by the presence or absence of these two junctions in this species. Removal of a portion of the isthmus also has no effect on embryo transport (Land et al., 1987; McComb et al., 1981). Together, these studies suggest that the presence of a sphincter in the AIJ and isthmic region of the oviduct are not required for normal embryo transport, at least in rabbits.

Ciliary activity

The oviduct epithelium is populated by ciliated cells and nonciliated secretory cells. The majority of the ciliated cells are in the infundibulum and ampulla regions of the oviduct. These cells have hair-like projections known as cilia, extending out of the apical membrane of the cell towards the lumen of the oviduct. Cilia contain axonemes that enable ciliary beating (Fig. 2A). The axoneme is made up of a bundle of microtubules wherein two singlet microtubules are encircled by nine doublets (Fig. 2B). Attached to one of the tubules in a doublet is a protein called dynein, which drives ciliary movement by reaching to a tubule in the adjacent doublet (Raedt et al., 2015). Ciliary beating serves to sweep mucus and other debris off the epithelium of many organs including the respiratory tract and the oviduct (Lodish, 2016). Motile cilia of the oviductal epithelium hydrolyze ATP to create a microtubule movement, generating beat, producing a current, which helps to move the embryo towards the uterus. Changes in the characteristics of the cilia such as orientation and ciliary beat frequency (CBF) can drastically alter oviductal fluid flow, and thus affect embryo transport.

Fig. 2 An illustration of cilia structure. (A) A longitudinal section of the cilia. (B) Cross-sections of the cilia. Arrows in (B) showing the direction of the active stroke of cilia. This direction is organized by the direction of the basal foot and the orientation of axoneme.

Ciliary orientation

The direction of oviductal fluid flow is from the ovary towards the uterus in most studied mammals, with the exception of the pig, wherein the flow in the isthmus is from ovary to uterus (Gaddum-Rosse and Blandau, 1976). The direction of fluid flow is coupled with the orientation of the cilia as seen by the change of mucociliary flow in response to surgical reversal of a segment of ciliated tissue. The cilia are oriented in the direction that the basal foots are pointed to (Fig. 2B). The basal foot designates the direction of active stroke of the ciliary beating. Schatz and colleagues showed that the mucus transport relies on the synchronous alignment of each cilium in relation to its neighbor (Schatz et al., 2013). In the rabbit, surgical reversal of ampulla delayed embryo transport whereas reversal of isthmus did not, suggesting that the direction of cilia beat modulates embryo transport (Nagasaka, 1984; Land et al., 1987; Eddy et al., 1978). A recent study shows that *Celsr1* (Cadherin EGF LAG Seven-Pass G-Type Receptor 1) gene is required for oviduct cilia orientation as a loss of *Celsr* expression leads to abnormal cilia polarity and random directions of beating (Shi et al., 2014). These findings indicate that the orientation of the ciliary beat governs the direction of the fluid flow.

Ciliary beat frequency

Ciliary beat frequency (CBF) is an indicator of mucociliary function. The CBF in the oviduct remains relatively constant, whilst adjusting in response to changes in fluid viscosity and content. The ability to prevent the collapse of mucociliary transport under fluctuating viscosities is called autoregulation. When challenged with viscous loads, cilia auto-regulate by slowing CBF to a frequency that can be maintained. The ability to auto-regulate is a result of a member of the transient receptor potential (TRP) family, TRPV-4, present in the cilia (Andrade et al., 2005). Calcium has been shown to increase CBF in the airway and oviductal epithelium (Lorenzo et al., 2008; Fernandes et al., 2008; Teilmann et al., 2005). Additionally, activation of TRPV-4 results in an influx of calcium into the cell, hence increasing the CBF. The effect of calcium on increasing CBF reaches the maximum at 350 nM concentration in vitro (Lansley and Sanderson, 1999).

Besides viscosity, CBF is also regulated by sex steroid hormones. P_4 represses CBF, while E_2 opposes the action of P_4 (Mahmood et al., 1998). Classical and membrane progesterone receptors (PGRs and mPGRs) are expressed in human and mouse oviduct (Teilmann et al., 2006; Nutu et al., 2009). The rapid reduction of CBF in response to P_4 is mediated through PGRs (Bylander et al., 2013; Bylander et al., 2010). Ciliated cell function can also be modulated by E_2 signal as CBF is reduced when estrogen receptor α (ESR1) is absent from mouse oviductal epithelial cells (Li et al., 2017). PGE_2 also increases CBF in rabbit and hamster oviduct by modulating calcium influx (Hermoso et al., 2001; Verdugo, 1980). In vitro studies have shown that $PGF_{2\alpha}$ activates its receptor, resulting in the release of intracellular calcium. Increased intracellular calcium levels alternate electrical membrane potential, and subsequently increase CBF (Villalon et al., 1989). Additionally, an inflammatory cytokine, interleukin-6 (IL-6), at high concentration decreases the CBF in human Fallopian tubes (Papathanasiou et al., 2008). These findings suggest that the CBF of the oviductal ciliated cells can be directly regulated by P_4 , E_2 , and other factors such as PGs and IL-6.

Oviductal fluid

Oviducts are filled with tubal fluid that not only nourishes and protects the pre-implantation embryo, it also aids in embryo transport to the implantation site. The rate of fluid flow is determined by variations in fluid volume as well as protein content and concentration. These variations are a result of excretions from the secretory cells of the oviductal epithelium, as well as selective diffusion of plasma from the adjacent artery, called "transudation" (Fig. 1) (Leese, 1988).

The volume of oviductal fluid varies between species and between each stage of estrous cycle within a species. In mammals, oviductal fluid production is highest at estrus and lowest at diestrus (Leese et al., 2001). Studies in many different species have shown that oviductal fluid volume increases in response to E_2 and decreases in response to P_4 . It is likely that E_2 and P_4 affect fluid volume by altering the gene expression level of aquaporins (AQPs) on the oviductal epithelium (Branes et al., 2005). AQPs allow water to be transported across the plasma membrane, thus, changes in their expression alter water availability in the oviduct. Expression of AQP1, AQP5, AQP8, and AQP9 have been detected in the oviduct of several species, including humans, pigs, rats, and mice (Huang et al., 2006; Skowronski et al., 2011; Branes et al., 2005). In pigs, AQP1, AQP5, and AQP9 protein expression fluctuates in response to the estrous cycle, reaching their peak expression when E_2 level is elevated. Similarly in rats, expression of AQP9 in the oviductal epithelium is highest at proestrus and estrus. AQPs expression levels coincide with a high oviductal fluid volume in the oviduct, which may explain their role in water transport to the oviductal lumen during proestrus and estrus. Taken together, these findings implicate that steroid hormones, E_2 and P_4 , are the underlying regulators of fluid volume fluctuation in the oviduct in part by altering water transport channels.

Oviductal proteins

While E_2 and P_4 work together to control oviductal fluid volume, they also regulate protein secretion from the secretory cells of the oviductal epithelium. These secreted proteins, either directly or indirectly facilitate embryo transport.

Among all oviductal proteins, mucins and uteroglobins maintain the process of embryo transport by preventing embryo implantation in the oviduct. This implantation of the embryo outside the uterus is one of the pregnancy complications called ectopic pregnancy. In the oviduct, mucins are large glycoproteins that act to lubricate the oviductal lumen with antimicrobial properties (Lagow et al., 1999). Mucin 1, in particular, is a large cell surface protein that inhibits cellular adhesion (Al-Azemi et al., 2009). It acts as a barrier between preimplantation embryos and the oviduct, preventing premature implantation (Aplin, 1999). Another molecule that directly impacts embryo transport is uteroglobin, which is a small protein expressed in the human Fallopian tube. Women with pelvic inflammatory disease (PID) have been associated with reduced levels of uteroglobin, specifically

at the ectopic implantation site in the Fallopian tube (Quintar et al., 2008). These findings suggest that mucins and uteroglobin may be necessary to prevent implantation of the embryo within the Fallopian tube.

Common Risk Factors Impair Embryo Transport

Some environmental and genetic factors can impair embryo transport. Studies have shown cigarette smoking slows muscle contraction and decreases CBF, causing a reduction in embryo transport. These physiological changes impair oocyte pick-up in the oviduct and lead to reduced fertility (Riveles et al., 2007; Knoll et al., 1995; Gieseke and Talbot, 2005; Knoll and Talbot, 1998). In vitro fertilization (IVF) patients, cigarette smoking also induces a much higher rate of miscarriage and ectopic pregnancy (Waylen et al., 2009). Other factors that also affect fertility are environmental contaminants, especially endocrine disruptors such as bisphenol A and S (BPA and BPS), and their chemical derivatives. These chemicals are common in our daily lives and act as weak ligands for ESRs. In the female reproductive system, BPA and BPS affect the functions of the oviducts, uterus, and ovaries, potentially inducing fertility defect (Ziv-Gal and Flaws, 2016). Treatment of BPA to pregnant mice causes embryo retention in the oviduct (Xiao et al., 2011). The pesticide, methoxychlor (MXC), is another type of endocrine disruptor that accelerates embryo transport in the oviduct and causes pre-implantation embryonic loss (Cummings and Perreault, 1990). These works indicate that environmental toxicants disrupt the physiological function of the oviduct and lead to impaired embryo transport.

Genetic disorders such as primary ciliary dyskinesia (PCD) also reduces fertility. PCD is a condition where the physical structure of the cilia dynein arms is distorted, impairing ciliary beating (Zariwala et al., 2007). Women with PCD have a higher risk for ectopic pregnancy and subfertility (Halbert et al., 1997). Genetic mutations of dynein axonemal light chain 1 (*DNAL1*) and dynein axonemal heavy chain 5 (*DNAH5*) in humans cause a defect of the outer dynein arm of the cilia (Zariwala et al., 2007). Structural abnormalities in the cilia lead to dysfunctional ciliary activity, prolonging embryo transport and resulting in ectopic pregnancy (McComb et al., 1986). In summary, mutations of genes involved in ciliary function and exposure to environmental toxicants can lead to ciliary damage, contributes to ectopic pregnancy and reduced fertility.

Conclusion

The oviduct is responsible for gamete and embryo transport. Its role is pivotal for precise timing of implantation. To achieve successful embryo transport, the oviduct utilizes three mechanisms: muscle contraction, ciliary beating, and oviductal fluid. These mechanisms are largely regulated by sex hormones, E_2 and P_4 , in which E_2 increases the overall speed of transport and P_4 decreases transport speed. Embryo retention and prolonged embryo transport can lead to ectopic pregnancy, which can be life-threatening to the mothers. Early exit of the embryos from Fallopian tubes could also lead to failed embryo implantation.

Origin and Development of Primordial Germ Cells

Massimo De Felici, University of Rome Tor Vergata, Rome, Italy

© 2018 Elsevier Inc. All rights reserved.

Introduction

The establishment of germline is a process that has always fascinated the scientists. In mammals, the first observations about the putative precursors of the sperm and oocytes, termed primordial germ cells (PGCs), in the wall of the yolk sac of human embryo around 3rd week of gestation, go back to little more than one hundred years ago. From then, the route of mammalian PGCs toward the gonadal primordia inside the embryo proper, has been traced and some of developmental processes of these cells ending with their differentiation into oogonia or prospermatogonia within the developing gonads described. However, only from the eighties years onwards, thanks to development of methods for isolation, precise identification and in vitro culture of mouse PGCs together with the characterization of natural mutations and the use of transgenic animals, important information about the molecular mechanisms underlying these processes has been obtained. More recently, the use of in vitro models for human PGC-like cell specification is providing basic insights into such processes also in the human embryo.

Specification and Determination of Primordial Germ Cells

In the mouse embryo, putative PGCs can be first localized as a small population of about 40 cells positive for alkaline phosphatase at the base of the allantois in the extraembryonic mesoderm at around 7.25 *days post coitum* (dpc) (Ginsburg et al., 1990). Such cells were subsequently shown to originate from a few (about six) of the most proximal epiblast cells, immediately adjacent to the extraembryonic ectoderm (Lawson and Hage, 1994).

From these early observations, several in vivo and in vitro studies, mainly performed in the mouse, extensively reviewed by De Felici (2013, 2016), focused on local molecules able to induce germ cell specification (cell commitment toward a definite fate that can be reversed or transformed to another fate) and subsequently their determination (irreversible commitment toward a definite fate). These showed that prior to and at the beginning of gastrulation, growth factors known as bone morphogenic proteins (BMPs) secreted from the extraembryonic ectoderm (BMP4, BMP8b) and visceral endoderm (BMP2), ultimately converge on proximal epiblast cells to promote PGC specification. Signaling by the wntless and int 3 (WNT3) protein originating from the posterior visceral endoderm and epiblast itself, conferred a receptive environment for proximal epiblast cells for BMP4 response. In fact, the PGC precursors appear to be initially driven toward a somatic mesodermal fate by WNT3, to regain subsequently a latent pluripotency typical of PGCs. The transcription factor B lymphocyte-induced maturation protein 1 (BLIMP1, also known as PR domain zinc finger protein 1, PRDM1), is downstream BMP4 induction, and marks the origin of the mouse PGC precursors around 6.25 dpc. Shortly after, the expression of PRDM14, another transcription factor of the same family, further contributes to PGC specification. The RNA-binding protein LIN28 appears to play a role as an upstream regulator of the BLIMP1 transcript translation whereas one more transcription factor, the activating enhancer binding protein 2γ (AP-2γ), is probably downstream BLIMP1. Sal-like protein 4 (SALL4), cooperates with BLIMP1 in suppressing the somatic cell program (in particular, the expression of *Hox* genes), while PRDM14 is likely involved in reactivating pluripotency in the nascent PGCs (i.e., the expression of sex determining region Y-box 2, *Sox2*, gene).

The PGC precursors increase in number and move toward the posterior region of the embryo. During this phase, other proteins involved in germline specification begin to be expressed. Among these *DPPA3* (developmental pluripotency associated protein 3, also known as Stella or PGC7), involved in epigenetic reprogramming, and the hypoxia-inducible factor-2α (HIF-2α), presumably contribute to regulate the expression of *Pou5f1* (also known as *Oct4*) gene in PGCs. The precise roles of *Oct4* and other key pluripotency genes such as *Sox2*, and *Nanog*, expressed at high level by the specified PGCs, remains to be clarified. Finally, mouse PGC determination is thought to occur in the extraembryonic mesoderm at the base of the allantois. This process is associated to high tissue nonspecific alkaline phosphatase (TNAP) activity, the expression of the tyrosine kinase receptor Kit and of the RNA-binding proteins, Nanos3, T-cell restricted intracellular antigen-1 related (TIAR), and dead-end protein homolog 1 (DND1). While the function of TNAP is unknown, all other proteins play a role in the survival and/or proliferation of the PGC during the subsequent migration and colonization of the gonads (for a review, see De Felici and Farini, 2012).

Fuss (1911, 1912) and Felix (1911) were probably the first to describe the extragonadal location of PGCs in human embryos. The place where PGCs were identified around the end of the 3rd week of gestation, is the same as in the mouse: the wall of the yolk sac at the angle with the allantois. The putative PGCs were distinguished by their large size, spherical shape, a prominent nucleolus, and the presence of abundant glycogen granules in the cytoplasm. Subsequently, histochemical methods for periodic acid-Schiff (PAS)-positive materials and alkaline phosphatase activity were applied to identify human PGCs (McKay et al., 1953). Only recently, the first gene and protein expression data of human PGCs at different stages of development were produced (Kobayashi et al., 2017 and references herein). Noteworthy, these studies show that gene expression patterns in early postmigrating human 7th–9th week PGCs are similar to mouse PGCs of comparable stages. Some important differences have been, however, described. In particular, while the *Sox2* gene is essential for mouse PGC development, its human counterpart is not expressed in PGCs which instead express *SOX17*. Moreover, human PGCs do not express significant level of PRDM14, while they express Kruppel-like factor

4 (*KLF4*), a transcription factor involved in pluripotency maintenance not expressed in mouse PGCs. Recently using the *Cynomolgus macaque*, PGCs were first identified in the amnios wall of the periimplantation embryo at 11 days of conception (Sasaki et al., 2016).

To compensate for the lack of information about the molecular mechanisms of PGC formation in the human embryo, in vitro culture systems based on the possibility to induce embryonic stem (ES) cells derived or induced pluripotent stem (iPS) cells to develop into specific cell lineages including the germline are now available (for a review, see De Felici, 2013). Using such models, it was shown that human ES and iPS cells possess a certain propensity to spontaneously differentiate into human PGC-like cells that can be increased with the addition to the culture medium of BMPs, the same growth factors governing the formation of mouse PGCs. Small changes in stem cell culture conditions or coculture onto human fetal gonad stromal cell, or mouse embryonic fibroblast monolayers in the presence of basic fibroblast growth factor (bFGF), have been also reported to favor the formation of hPGCLC. In addition, silencing the *DAZ* family and *NANOS3* genes in human ES cells resulted in a marked reduction in their capability to give rise to PGCLCs. Recently, defined and stepwise robust differentiation systems for inducing premigratory hPGCLC from iPS cells were reported (Sasaki et al., 2015).

Considering the available information and the different organization of the mouse and human embryos, a hypothetical model for the human PGC formation can be drawn (Fig. 1).

PGC Migration

Mouse PGCs are described to initiate active migration just after specification. Time-lapse photography documented that OCT4-GFP/AP positive cells actively migrated into the allantois/posterior embryo. Before PGCs begin this first step of their journey, however, they express factors associated with cell to cell adhesion such as interferon-inducing transmembrane proteins (IFITM) and E-cadherin. Shortly after PGCs arrive within the hindgut likely along morphogenetic movements, they are likely to receive signals that first promote random motility, and then induce directional migration toward the gonadal ridges. E-cadherin expression disappears in PGCs located in the hindgut, whereas hindgut epithelium expresses high levels of this adhesion protein. Together with decreased E-cadherin expression, receptor tyrosine kinase activity via Kit/KL interactions probably is a factor promoting PGC motility (Fig. 2). Besides Kit/KL activity, another receptor tyrosine kinase/ligand pair, the orphan receptor 2 (ROR2)/WNT5A, was found to favor polarization and elongation of PGCs; disruption of either components caused PGCs to round up and cease migration.

The final part of the mouse PGC journey occurs between 10.5 and 11.5 dpc and requires their migration from the hindgut through the dorsal mesentery to the gonadal ridges. In the absence of TGF β signaling (ALK5 deficiency), PGC migration out of the hindgut was promoted, likely because of the reduced deposition of collagen type I surrounding the gut. In fact, migratory PGCs adhere strongly to collagen; therefore, reduced collagen type I along the gut may result in reduced adhesion, facilitating migration into the dorsal mesentery and gonadal ridges. In this migratory stage, chemokine signals, likely provide attractants and homing mechanisms. In particular, stromal cell-derived factor 1 (SDF1), from neighboring mesenchyme and the gonadal ridges, interacting

Fig. 1 After implantation and before gastrulation, around the end of the 2th week of gestation, the human embryo consists of a flat disk with two cell layers, epiblast, and hypoblast. It seems plausible that at this stage, the precursors of PGCs (pPGCs) are set aside within the posterior region of the epiblast following the action of BMP signals coming from trophoblastic tissue (including the developing syncytio- and cytotrophoblast) immediately surrounding the periphery of the embryonic disk (or perhaps from the amnioblasts lining the amnios and located above the epiblast) and the hypoblast. A, anterior; P, posterior.

Fig. 2 A mouse PGCs cultured in the presence of a gradient of KL stained for TNAP show a motile phenotype with a lamellipodium/filopodium at the leading edge (arrows) and uropodium at the trailing edge indicated (arrowhead).

with PGCs via its G-protein coupled receptor, CXCR4 (chemokine C-X-C motif receptor 4), and KL, stimulating Kit, are candidate for such activities.

Other studies reported that cell–cell and cell–extracellular matrix (ECM) interactions are also critical for this last stage of PGC migration and gonad colonization. It was hypothesized that such interactions are required to maintain PGCs on the narrow path toward the gonad in the context of diffuse attractant signals. Interactions between PGCs and the ECM glycoproteins such as integrin $\beta 1$, laminin, fibronectin, and collagen IV, dependent on the stage of PGC migration, have been reported. In this regard, it is worthy to mention that integrin $\beta 1$ -deficient PGCs failed to colonize the gonads (for a review, see [De Felici et al., 2005](#)).

PGCs emigrating from the hindgut, were observed to extend long cellular processes that interacted with each other and their surroundings. Subsequent analysis revealed that E-cadherin expression was re-established once PGCs left the hindgut, and was concentrated with β -catenin at sites of PGC–PGC contacts. Moreover, treatment with E-cadherin-blocking antibodies prevented PGCs from directional migration in both in vitro and in vivo experiments, suggesting its role in mediating cell–cell interactions and promoting migration to the gonads.

Surprisingly, gonadal ridges are probably dispensable for the directional migration of PGCs, but required for their precise positioning at the final step of journey. In fact, in *Wt1* mutated mice in which gonadal ridges do not form, most of the PGCs reached the mesenchyme under the coelomic epithelium and no ectopic PGCs were noted; however, the precise positioning of PGCs was disrupted. Similarly, in null mutants for *Gata4*, gonadal ridges never form, however, the PGCs migrate and settle under the coelomic epithelium. Based on morphological observations, some authors claimed that the movement of PGCs from the allantois/yolk sac wall to the hindgut and then the gonadal ridges, might be explained by a simple passive translocation through first an enclosure in the endoderm forming the wall of the hindgut and then a transport by the proliferative expansion of this tissue into the very near gonadal ridges.

Active and passive translocation are applicable also for the journey of human PGCs towards the gonadal ridges. In the human embryo, the superior part of the yolk sac wall containing the PGCs, becomes incorporated in the developing gut during the lateral folding at 4th week of gestation, suggesting that the PGC translocation into the gut may be passive. The gonadal ridges are recognized by a bilateral thickening of the coelomic epithelium near the developing root of the gut mesentery in the posterior embryonic body cavity around 5th week. PGCs present in the endoderm of the gut epithelium were seen from the 5th week onwards. Thereafter, they leave the epithelium and invade the surrounding mesenchyme moving through the gut mesentery toward the gonadal ridges.

Electron microscopic studies describe human PGCs in vivo as having an irregular appearance and possessing pseudopodia during their journey toward the gonadal ridges. These features can be interpreted as a manifestation of active migration. An interpretation confirmed by several in vitro observations reporting that human PGCs show several characteristics of motile cells and can move actively both on cellular and ECM substrates. Such capability is probably used by PGCs to cover the distance of approximately 50 μ m separating the pre-aortic region from the gonadal ridges. Similarly, to mouse PGCs, migratory human PGCs appear to be surrounded by ECM components in which glycosaminoglycans have been histochemically detected. PGCs seem also interacting with the mesenchymal cells through different type of junctions, such as desmosomes, gap junctions, and focal contacts. [Møllgård et al. \(2010\)](#) observed that human PGCs preferentially ascended from the mesentery of the hindgut to the gonadal anlage by migration along autonomic nerve fibers close to the Schwann cells and proposed that these nerve fibers and/or Schwann cells may release chemoattractants supporting PGC migration. In humans, primary sites of ectopic germ cells are within the CNS but they are also seen in the pelvic region, the mediastinum and thorax.

No specific attractants have been identified for human PGCs although they have Kit and are surrounded by cells expressing KL and possess the CXCR4 receptor. The expression of transcripts for member of the olfactory receptor gene family in human PGCs from 10-week-old embryos makes this class of receptor additional candidates for PGC attractants.

During migration, human PGCs contain a large PAS-positive cytoplasmic store of glycogen and several lipid droplets. Following their arrival in the gonadal ridges, the glycogen content is diminished. Round mitochondria with a pale matrix and small tubular vesicular cristae were observed near the nucleus. They significantly increase in number during PGC migration and settlement in the gonadal ridges. Migratory human PGCs have less than 10 mitochondria, while 100 mitochondria are present in ovarian PGCs and 200 in oogonia. These observations suggest that PGCs might prevalently employ an anaerobic metabolism during migration and undergo a transition in their energy metabolism after reaching the gonadal ridges.

An extensive review of mouse and human PGC migration can be found in [De Felici \(2013, 2016\)](#).

Epigenetic Reprogramming

Epigenetics consists of stable heritable changes in gene expression not due to DNA sequence modifications. A unique characteristic of germline is the extensive epigenetics accompanying PGC development. Such process involves primarily DNA wide demethylation and changes of histone marks. This constitutes the so-called epigenome reprogramming or resetting that restores full germline potency for the transmission of genetic information to the next generations (for a review, see [De Felici, 2011](#)).

Immediately following specification, a marked reduction in heterochromatic histone H3K9me2 followed by an increase in repressive H3K27me3 and H2A/H4R3me2s occur in mouse PGC precursors. Such early changes are favored by a period of mitotic arrest and transcriptional quiescence occurring in such cells between 8.5 and 9.5 dpc ([Seki et al., 2007](#)).

Although DNA demethylation begins during this early phase, the bulk of DNA demethylation occurs in PGCs after gonad colonization (between 11.5 and 13.5 dpc). This is accompanied by changes in chromatin organization and loss of numerous histone modifications brought about by genome-wide histone replacement. This second wave of reprogramming includes complete X reactivation in female and the erasure of imprinting (a process by which certain genes are expressed in a parent-of-origin-specific manner), allowing the establishment of sex-specific imprints during the successive gametogenesis.

Evidence exists that DNA demethylation in mouse PGCs employs both a passive (DNA replication-dependent) and active mechanisms. A decrease in the protein level of the de novo methyltransferases DNMT3a and DNMT3b accompanies the PGC postspecification and gonad colonization periods while the maintenance methyltransferase DNMT1 is present but inactive. Active demethylation may involve the DNA repair pathway such as activation-induced cytidine deaminase (AID) and thymine DNA glycosylase (TDG) enzymes, ten-eleven translocation (TET) enzymes and poly (ADP-ribose) polymerase (PARP) activities.

In human PGCs, a few observations have been reported about DNA demethylation and chromatin changes. A timeline and some characteristics of these events are becoming, however, to be available also thanks to the in vitro models of PGC-like formation for stem cells described above (for a review, see [Tang et al., 2016](#)). Immunohistochemical studies and DNA methylome analyses of global 5 mC level showed that both female and male fetal germ cells are hypomethylated already at 5th–7th weeks of gestation when most of them are still migrating or have just arrived in the gonadal ridges. Concomitantly, PGCs undergo chromatin reorganization, X reactivation, and imprinting erasure. Like in mouse, consistent with global demethylation, UHRF1, a factor necessary for DNMT1 activity, was not detectable in proliferating PGCs/oogonia while de novo DNA methyltransferase DNMT3a and DNMT3b were repressed; as note TET1 and TET2 appeared enriched during this period. In human PGCs, demethylation of imprint controlled regions (ICRs) is completed, except for the insulin growth factor2 receptor (*IGF2R*) and the progression elevated gene-10 (*PEG10*) genes, before 7th week when most of PGCs are still migrating towards or are recently arrived into the gonadal ridges, indicating early epigenetic dynamics. Resembling mouse PGCs, despite global hypomethylation, potentially hazardous retrotransposons such as the SINE-VNTR-ALU (SVA) and endogenous retrovirus (ERV) elements remain methylated in human oogonia. Interestingly, in contrast to mouse prospermatogonia, which remain demethylated for only a few days, human prospermatogonia remain hypomethylated for weeks and only showed signs of re-methylation in the II trimesters (around 16th week onward).

As for histone marks, in human PGCs, H3K9me2 levels were persistently lower compared to soma, but it remained detectable in the nuclei. Although at week 4th human PGCs showed 2.5-fold enrichment of H3K27me3, the signal diminished gradually to half of that of soma by week 9th. H3K27me3 foci at the inactivated X chromosome were observed in soma but not in week 7th female PGCs, indicating reactivation of X. At around 16th–20th weeks male germ cells demonstrate absence/low levels of repressive H3K9me2, H3K27me3, and H3K9me3 modifications but high levels of permissive H3K9ac and H2A.Z marks. Remarkably, PGCLCs produced in vitro from human stem cells showed ongoing removal of parental imprinting, erasure of global DNA methylation and histone modifications like their in vivo PGC counterparts.

PGC Differentiation

After arrival in the gonadal ridges, PGCs differentiate into oogonia and prospermatogonia within the developing ovaries and testes, respectively. Both oogonia and prospermatogonia undergo a phase of active proliferation. In oogonia this phase is followed by a mitosis to meiosis switch from which the primary oocytes arise whereas prospermatogonia do not enter meiosis but undergo mitotic arrest into G0.

In the mouse, the transition of PGCs to oogonia or prospermatogonia occurs in a couple of days and is associated to the loss of the motile phenotype, the formation of germ cysts (or nests) due to incomplete cytodieresis, a second wave of epigenetic changes (see above) and the expression of germ cell specific genes such as *Ddx4* (or *Vasa*) and *Dazl*. During this time, no relevant morphological differences between oogonia and prospermatogonia are detectable although their transcriptome begins to diverge significantly in function of the irreversible commitment to oogenesis or spermatogenesis ([Sakashita et al., 2015](#); [Lei and Spradling, 2013](#)).

The sexual differentiation of PGCs is not cell autonomous, meaning that it is not determined by their own sex chromosome constitution. Instead, it is determined by the sexual phenotype of their somatic environment. In the mouse, testis determination is initiated between 10.5 and 11.5 dpc, by expression of the Y-chromosome gene, *SRY* (sex determining region Y chromosome), within the somatic cells, mainly the pre-Sertoli cells, whereas ovary differentiation is guided by the expression in the somatic compartment of at least two genes, namely *RSPO1* and *WNT4* (for a review, see [Ewen and Koopman, 2010](#)).

Since most of the studies focused on PGC sex differentiation into oogonia and prospermatogonia have been performed in the mouse where this process is rapidly followed to entering into meiosis and mitotic arrest, respectively, these two events have been

considered strictly associated to the commitment of PGCs to oogenesis or spermatogenesis. Actually, the decision between male and female germ cell fates is marked by environmental signals that control the expression of two master genes: *Stra8* (stimulated by retinoic acid gene 8), which is required for the initiation of meiosis in females, and *Nanos2*, which blocks *Stra8* expression in males and thereby prevents meiosis. One important environmental factor known to play a role in female-specific development is retinoic acid (RA), which activates *Stra8* in female germ cells (for a review, see Bowles and Koopman, 2007), however, the direct target/s of STRA8 are unknown (Tedesco et al., 2009). In the male, germ cells are protected from exposure to RA by Cyp26b1, an RA-metabolizing enzyme of the cytochrome P450 family that is produced by the Sertoli cells and the Leydig cells. The degradation of RA is likely necessary for arresting the prospermatogonia proliferation and at the same time to suppress entering meiosis (Trautmann et al., 2008). Despite the importance of RA inhibition in males, multiple lines of evidence indicate that additional secreted factors also play crucial roles in determining male germ cell differentiation. One candidate that has been proposed is the secreted male-specific Fgf9. This growth factor signaling maintains the expression of pluripotency-related genes, and actively suppresses entry into meiosis by activating *Nanos2* expression (Barrios et al., 2010) via the transient activation of the Cripto/Nodal pathway (Spiller et al., 2012). A role of prostaglandin D₂ (PGD₂), in this process has been also proposed. Both somatic- and germ cell-produced PGD₂, acting in both a paracrine and an autocrine manner, play a role in the regulation of male fetal germ cell differentiation (Moniot et al., 2014). In addition, the transmembrane protein SDMG1 (sexually dimorphic, expressed in male gonads 1, also known as TMEM184a), associated with endosomes and specifically secreted by Sertoli cells, may be involved in such repressive signaling (Best et al., 2008).

A recent report indicated, however, that the beginning of meiosis and germ cell commitment into oogenesis are dissociable events. In fact, in the mouse *Stra8*-deficient ovarian germ cells grow and differentiate into oocyte-like cells that can be ovulated and fertilized (Dokshin et al., 2013). The drivers of oocyte differentiation are unknown, although the transcription factors SOHL1 and 2 can be involved (Shin et al., 2017). Likewise signaling mechanisms responsible for initiating male commitment of the germ cells may be different from the molecular signals/pathways initiating mitotic arrest and meiosis inhibition. For example, in human, mitotic arrest of germ cells occurs considerably later than somatic sex determination and sex cord formation (and probably germ cell sex determination) and prospermatogonia apparently retain proliferative activity until late gestational period; during this period, accumulating numbers of germ cells appear to exit the cell cycle in a relatively unsynchronised manner.

Human PGCs arrived into the gonadal ridges are rapidly surrounded by somatic cells. The differentiation of PGCs into oogonia occurs during the 9th week of gestation. Oogonia tend to form clusters of dividing cells joined by rims of cytoplasm, termed intercellular bridges, originated by incomplete division of the cell body during cytodieresis. The mitotic proliferation of oogonia lasts several weeks and overlaps the period of their entry into meiosis (10th–11th weeks). Actually, until the 5th month of fetal life, mitotic oogonia and primary oocytes in different stages of meiosis coexist. In the male, PGCs enclosed within seminiferous sex cords become prospermatogonia. Testis differentiation is marked by the expression of sex determining region Y (SRY) and SRY-box 9 (SOX9) genes at 5–6 weeks. Thereafter, sex cords, formed from Sertoli cells and prospermatogonia, become increasingly evident within the testis from the 7th week during late embryonic life. During the first trimester, prospermatogonia are mitotically active and continue to express markers typical of pluripotent cells and PGCs such as OCT4, SSEA1, DDX4 (Vasa), Nanog, and KIT. During the second trimester, most but not all prospermatogonia progressively lose mitotic activity together with the pluripotency and PGC markers.

In the human fetal ovary, the first signs of meiosis initiation are apparent in oogonia around 10 weeks postfertilization. At this stage, meiosis initiation appears strikingly asynchronous, as while more and more germ cells initiate meiosis some oogonia go on proliferating until at least 16 weeks. Interestingly, after 12th week, oogonia seem to segregate into two populations of KIT/OCT4 located at the periphery and VASA positive cells toward the center of the ovary. The latter showing the formation of the synaptonemal complex indicating meiotic entry. Contrary to the antero-posterior wave of meiosis initiation reported in fetal mouse ovaries, this radial gradient in human ovaries suggests the existence of species differentiation in the initiation signals, with local somatic cell interaction operating in human versus diffusible cues in mice. Like in the mouse, RA is a possible intraovarian factor involved in meiosis initiation in the human ovary, although it remains, however, to be determined how the extensive asynchrony of the beginning and progression of this process is regulated (Le Bouffant et al., 2010).

FETAL DEVELOPMENT

Formation and Growth of the Fetus

Alison J Forhead, University of Cambridge, Cambridge, United Kingdom; and Oxford Brookes University, Oxford, United Kingdom

Abigail L Fowden, University of Cambridge, Cambridge, United Kingdom

© 2018 Elsevier Inc. All rights reserved.

The conceptus develops from a single fertilized egg into a complex multicellular organism by processes of cell proliferation, growth, and differentiation within the uterus. After organogenesis, the major period of body growth occurs in fetal life, during the second and third trimesters of human pregnancy. Fetal growth follows an orderly and coordinated increase in body weight and length, which is coupled with a proportionate increase in organ weights and their functional development. Normal fetal growth and maturation is essential for both the survival of the offspring at birth and for longer term health in adult life.

Measurement of Fetal Growth

Fetal growth can be assessed by a range of clinical and experimental methods. End-point measurements, such as body weight, length, and adiposity at the time of delivery, are simple indicators of intrauterine growth. It is also possible to measure growth rate while the fetus is developing within the uterus. Ultrasound scanning can be used to make a variety of measurements of growth at different gestational ages. In clinical practice, the most common biometric measurements include biparietal diameter (diameter of a cross-section of the head or skull), femur bone length and abdominal circumference, and these values are combined to estimate the body weight of the fetus.

Using ultrasound data from many individuals, a series of growth charts can be generated to estimate the percentile and the growth trajectory of the fetus. These growth charts have recently been updated by the World Health Organization using data obtained in a multinational study. Longitudinal measurements were made from 14 to 40 weeks in singleton fetuses, where the pregnant women were recruited from middle to high income backgrounds to ensure good nutritional status ([Kiserud et al., 2017; Fig. 1](#)). Fetal growth charts can be used to diagnose abnormalities in intrauterine growth, particularly if fetal growth deviates from its previous trajectory. Estimated fetal body weight less than the 10th centile or greater than the 90th centile indicates a fetus that is small- or large-for-gestational age (SGA and LGA), respectively.

Experimentally, fetal growth has been monitored in large animal models, such as sheep, using both end-point and continuous intrauterine measurements. In the sheep fetus, indwelling growth devices measure the crown-rump length and abdominal circumference over a period of late gestation and incremental growth rates have been demonstrated in well-fed ewes with stable maternal plasma glucose concentrations ([Mellor and Matheson, 1979; Fig. 2](#)). Collectively, the ultrasound and experimental techniques have shown, in many species including the human, that fetal growth is greatest in absolute terms in the later stages of gestation. Close to term, however, the growth rate of the fetus slows as the developing tissues switch from cell proliferation to differentiation and functional maturation, in preparation for birth.

Control of Fetal Growth

The growth of the fetus is driven primarily by the genetic potential of the individual inherited at conception. Intrauterine growth and development, however, can be modified by a variety of factors including physiological, nutritional, environmental, and clinical conditions with consequences for size at birth. Many of these factors interact with each other to generate a wider range of birth weights in the human and animal population than predicted by genotype alone. These factors can be divided into those that originate in (1) the mother, (2) the placenta, and (3) the fetus itself ([Fig. 3](#)).

Maternal Factors

Maternal size

The size of the mother influences the growth rate of the fetus. This may be due to (i) the inherited genetic potential for fetal growth, as paternal height also correlates with birth weight, (ii) the size of the uterus and/or (iii) the body composition and energy reserves of the mother before and during pregnancy. The relative contributions of the genetic and uterine environment in determining fetal growth, however, are difficult to separate. In human populations, both maternal height and body mass index, and paternal height, correlate with offspring birth weight; further analysis shows that neonatal adiposity and head circumference are predicted by maternal height and body mass index, while limb lengths are more strongly associated with paternal height ([Pomeroy et al., 2015](#)). In assisted pregnancies where egg donation was used, the birth weight of the infant correlated with the weight and height

Fig. 1 Growth charts and percentiles for biparietal (*outer–inner*) diameter, head circumference, abdominal circumference, femur length, humerus length, and estimated body weight in human fetuses from 14 to 40 weeks of gestation. Taken from Kiserud, T., Piaggio, G., Carroli, G., Widmer, M., Carvalho, J., Neerup Jensen, L., Giordano, D., Cecatti, J.G., Abdel Aleem, H., Talegawkar, S.A., Benachi, A., Diemert, A., Tshetu Kitoto, A., Thinkhamrop, J., Lumbiganon, P., Tabor, A., Kriplani, A., Gonzalez Perez, R., Hecher, K., Hanson, M.A., Gülmezoglu, A.M. and Platt, L.D. (2017). of the recipient, but not with measurements from the biological donor mother (Brooks et al., 1995). This suggests that the intra-uterine environment may have a greater role in mediating the effect of maternal size on offspring birth weight than the genetic influence of the mother.

The larger the uterus, the more space is available for growth of both the placenta and fetus and equally, a small uterus can limit the ability of the placenta and fetus to grow to their genetic potential. The effect of uterine size on fetal growth was demonstrated in classical experiments by Walton and Hammond (1938). They developed the technique of artificial insemination to cross breed Shire horses and Shetland ponies. When a Shetland pony mare was inseminated by a Shire horse stallion, the foal produced was three times smaller than the foal conceived by a Shire horse mother and Shetland pony father (Walton and Hammond, 1938; Fig. 4). These studies showed that the size of the uterus can determine the size of the newborn foal, such that the birth weight of the offspring is a function of maternal body weight, around 8% in these experiments. Furthermore, the differences in foal size and body composition at birth persisted into later life.

Maternal nutrition

Maternal nutrition is a key regulator of fetal growth as the mother provides the macro- and micronutrients that both the fetus and placenta require to grow. Several experimental and epidemiological studies have shown that under-nutrition of the mother impairs fetal growth (Sferruzzi-Perri et al., 2013).

Fig. 2 Growth rates for crown-rump length and abdominal circumference using indwelling growth measuring devices in a sheep fetus during late gestation (term ~145 days). Redrawn from Mellor, D.J. and Matheson, I.C. (1979). Daily changes in the curved crown rump length of individual sheep foetuses during the last 60 days of pregnancy and the effects of different levels of maternal nutrition. *Quarterly Journal of Experimental Physiology* **64**, 119–131.

Fig. 3 Factors that influence the growth of the fetus.

Using growth-measuring devices in sheep fetuses, the growth rates of the axial skeleton and abdominal circumference were monitored before, during and after a 10-day period of maternal under-nutrition (Mellor and Murray, 1982; Fig. 5). Maternal plasma glucose levels fell when the mother was under-nourished and the growth rates measured in the fetus were suppressed. When the mother was re-fed to normal levels, maternal plasma glucose concentration returned to normal and the growth of the fetus was restored to the rate observed before the period of under-nutrition.

The Dutch Winter Hunger study is a unique opportunity to examine the effects of maternal under-nutrition on fetal growth in the human population. During World War II, parts of occupied Netherlands were severely rationed by the German army such that, for the last 6 months of the war, the food intake of the people of Western Netherlands, which included Amsterdam, Rotterdam, and The Hague, was reduced to <1000 calories per day. Pregnant women in the third trimester during this time did not show normal weight gain and their babies were around 200–300 g lighter in birth weight (Smith, 1947; Lumey, 1998; Table 1).

Other maternal factors

Fetal growth is also affected by a variety of interacting maternal factors. Parity influences growth of the fetus, whereby first-born offspring are usually smaller than subsequent siblings, in part, as a consequence of changes in uterine size. Extreme ends of maternal

Fig. 4 Parents and offspring of reciprocal Shetland–Shire crosses to show consequences of maternal size for fetal growth. Taken from Walton, A. and Hammond, J. (1938). The maternal effects on growth and conformation in Shire horse–Shetland pony crosses. *Proceedings of the Royal Society London B* **125**, 311–335.

Fig. 5 Effect of maternal nutrition on growth rate of crown-rump length and abdominal circumference in a sheep fetus during late gestation. Redrawn from Mellor, D.J. and Murray, L. (1982). Effects of rate of increase in fetal girth of refeeding ewes after short periods of severe undernutrition during late gestation. *Research in Veterinary Science* **32**, 377–382.

age have been linked to impaired fetal growth, with both teenage and older (>35 years) mothers more likely to give birth to SGA offspring (Restrepo-Méndez et al., 2015). Low birth weight associated with young maternal age may be a result of suboptimal partitioning of resources between the fetus and mother that is still growing herself. In older mothers, preexisting disease may impair placental and fetal growth. These observations, however, are confounded by other factors linked with young and older pregnant women, such as socioeconomic class and nutritional status.

Table 1 Mean placental and birth weights, and placental efficiency, in the Dutch Hunger Winter study

	Control	Trimester of famine exposure		
		1st	2nd	3rd
Placental weight (g)	636	647	611	547
Birth weight (g)	3379	3361	3435	3130
Placental efficiency (g/g)	5.31	5.19	5.62	5.72

Data taken from Lumey, L.H. (1998). Compensatory placental growth after restricted maternal nutrition in early pregnancy. *Placenta* 19, 105–111.

Low birth weight offspring are commonly associated with maternal smoking, chronic stress, alcohol, and drug use, lower socioeconomic class and medical conditions such as preeclampsia, malaria, chronic hypertension, and renal disease (Kramer, 1987). Maternal diabetes and obesity lead to increased incidences of both SGA and LGA offspring. Habitation in the chronic hypoxic environment at high altitude lowers birth weight by approximately 100 g for every 1000 m ascent in altitude, especially in nonnative populations (Moore, 2003).

Placental Factors

The placenta is the interface between the mother and fetus, and ultimately regulates the transfer of nutrients and oxygen from the maternal to fetal circulation. Therefore, the size, structural development and functional transport capacity of the placenta are key factors that affect fetal growth. In many animal species, including humans, the size and growth of the fetus correlates with the size of the placenta, although it is important to consider the common genetic make-up of the fetus and the fetal-derived placental tissues.

After implantation, the early development of the placenta is essential for normal growth of the embryo and fetus. In some species, such as the sheep, the placenta grows at a rapid rate in early gestation and plateaus in size by mid-gestation, while in human pregnancy, the placenta continues to grow at a steady rate throughout gestation. During late gestation, however, the rise in fetal body weight occurs at a faster rate than the change in placental weight which means that the microstructural and functional properties of the placenta, and the transfer of nutrients, are increased to support fetal growth.

The exchange of nutrients, respiratory gasses, water, and waste products between the mother and fetus is governed by the structural development of the placenta. According to Fick's law of diffusion, the transfer rate of freely-permeable substances such as oxygen is dependent on the placental surface area, thickness of the diffusion pathway and the concentration gradient between the maternal and fetal circulations. The concentration gradient is maintained by adequate maternal oxygenation and nutrient status, and uteroplacental blood flow. For nutrients transferred by facilitated diffusion, such as glucose, the placental expression of transporter proteins contributes to the rate of transfer. Specific transporters are also essential for active transfer processes which use energy to transport nutrients, such as amino acids needed for protein synthesis, from mother to fetus against a concentration gradient.

Several experimental models demonstrate the importance of placental size in determining fetal growth. First, the consequences of decreasing placental size from the outset of the pregnancy have been examined in sheep. A number of the implantation sites in the uterus, the caruncles, were surgically removed before mating; these are the sites where the placental cotyledons form during pregnancy. Removal of some of these caruncles led to a reduction in the number of placental cotyledons and subsequently impaired the growth of the fetus (Robinson et al., 1994; Fig. 6). Many of the remaining placental sites were overgrown in an attempt to compensate for the reduction in number, but placental weight overall was still lower which caused poor fetal growth. Placental restriction can also be induced experimentally in rats by ligation of the uteroplacental blood vessels which impairs placental blood flow and leads to significant growth retardation of the offspring.

Data from the Dutch Hunger Winter study also demonstrates the effects of maternal under-nutrition on placental and thereby fetal growth (Lumey, 1998; Table 1). These effects depended on the stage of gestation when the famine occurred. For women in the first trimester of pregnancy during the famine, there was an increase in the size of the placenta at birth and the fetuses were born a normal size; the early growth of the placenta was stimulated by maternal under-nutrition and this was able to support normal fetal growth. In the second trimester, placental size was reduced at birth, but offspring birth weight was normal and overall placental efficiency was significantly improved (the ratio of fetal weight to placental weight, as grams of fetus produced for each gram of placenta). This indicates that the placenta increased its functional capacity and effectiveness in nutrient delivery to maintain fetal growth despite being of a smaller size. Finally, when women were exposed to the famine in the third trimester, birth weight was lower and this was related to a profound reduction in placental weight; although the placenta improved its efficiency, the offspring were born smaller than normal.

The placenta may also contribute to the control of growth in utero by the production and metabolism of hormones that have consequences for maternal and fetal physiology. Placental hormones influence maternal physiology and metabolism in a way that promotes nutrient delivery to the fetus. Placental lactogen induces a degree of insulin resistance in the mother such that less glucose

Fig. 6 Effect of reduction in placental size by carunclectomy on fetal growth in sheep. Both fetuses and their placentomes were measured at 127–128 days of gestation (term ~145 days): the upper fetus was taken from a ewe where uterine caruncles were removed before pregnancy, while the lower fetus was taken from a control ewe. Taken from Robinson, J.S., Owens, J.A. and Owens, P.C. (1994). Fetal growth and fetal growth retardation, In Thornburn, G.D. and Harding, R. (eds.) *Textbook of fetal physiology*, pp. 83–94, Oxford: Oxford University Press.

is taken up by maternal tissues and more is readily available for transfer to the fetus. In addition, the pregnancy steroid hormones, progesterone and estrogen, stimulate a range of maternal adaptations in cardiovascular, respiratory and metabolic systems, as well as regulating the contractile activity of the uterine muscles.

The placenta is also the site of metabolism of maternal hormones that can influence fetal growth and development. For instance, the transfer of maternal glucocorticoids to the fetus is limited by the placental enzyme 11β -hydroxysteroid dehydrogenase. This enzyme converts glucocorticoids to biologically-inactive metabolites and thereby protects the fetus from the growth-retarding effects of glucocorticoids from the mother. The placenta also acts as a partial barrier to the transfer of thyroid hormones; placental expression of the type III deiodinase enzyme metabolizes thyroid hormones to inactive forms and regulates circulating thyroid hormone levels in both the placental and fetal circulations.

Fetal Factors

Genetics of the fetus

The genetic makeup or genome of the offspring (which also contributes to the genome of the placenta) influences fetal growth and size at birth. In human populations with diverse backgrounds, there is variation in birth weights between different ethnic groups. For instance, a study in the USA examined the birth weights of infants born 2009–12 from 14 defined races (Morisaki et al., 2017). Compared to non-Hispanic white infants, Japanese babies were on average 289 g lighter and Samoan babies were 126 g heavier. Approximately 60% of the variation in birth weight between ethnic groups, however, was accounted for by differences in the incidence of prematurity, maternal height, body mass index, and gestational weight gain. After adjustment for maternal and socioeconomic factors, black infants were the smallest and American Indians were the largest at delivery.

Several of the genes that are important for placental and fetal growth are imprinted genes (genes that are preferentially expressed from either the maternal or paternal copy). Paternally-expressed genes, such as insulin-like growth factor-II (IGFII), promote fetoplacental growth, whereas maternally-expressed genes, such as the IGF type 2 receptor, tend to restrict growth. The conflict theory proposes that the imprinted genes inherited from the father act to maximize growth and survival of the offspring, while those inherited from the mother limit growth of the fetus, in order to conserve resources for the mother and any future offspring. However, the maternal and fetal genomes also have to interact cooperatively during pregnancy to ensure delivery of a viable infant at term.

There are consequences of genetic defects in the fetus for its ability to grow normally. Genetic defects can affect overall body growth or growth of specific tissues to influence birth size. These defects may be due to single gene mutations such as osteogenesis imperfecta, a brittle bone disease where the individual cannot synthesize collagen normally which has consequences for development of the skeletomuscular system. Alternatively, the defect may involve whole chromosomes; for example, Down's syndrome is due to an extra chromosome 21 which reduces birth weight by 240–300 g, as well as leading to facial and other abnormalities in development. Growth defects can also arise from changes in the expression of single genes without any alterations in chromosome number or DNA sequence. For instance, over-expression of the *IGF2* gene on chromosome 11 due to changes in DNA methylation and imprinting status in Beckwith Wiedemann syndrome typically leads to overgrowth of specific organs and larger than normal birth weight.

The sex of the fetus influences the pattern of growth before birth and newborn weight: female fetuses are smaller than male fetuses at the same gestational age and at birth. Multiple offspring in a pregnancy are also smaller than singleton fetuses in human and other species. Growth of individual fetuses may be compromised by the number of fetuses in a pregnancy by competition for resources and uterine space for placental development.

Hormones of the fetus

There are a variety of hormones produced by the fetus that can influence its body growth and organ development, including insulin, IGFs, thyroid hormones, glucocorticoids, and leptin (Fowden and Forhead, 2009, 2013; Sferruzzi-Perri et al., 2013). Experimental and clinical studies have demonstrated that changes in the levels of these hormones in utero have consequences for the growth of the fetus and placenta (Table 2). In human infants at term, birth weight correlates positively with umbilical cord blood concentrations of insulin, IGF1, thyroxine, and leptin. Hormones act as signals of the intrauterine environment to both fetal and placental tissues, and serve to match the growth and development of the fetus with the levels of oxygen and nutrients available. They have actions on cell proliferation, growth, differentiation, metabolism, and function in a wide range of fetal tissues, and can influence placental growth and transport capacity.

Insulin promotes growth of the fetus, especially fat mass. In fetal tissues, it stimulates uptake of glucose and amino acids, and therefore glucose utilization and protein synthesis, which encourages further transplacental movement of glucose to the fetus down the maternal-fetal concentration gradient. Insulin is responsible for overgrowth of babies born to mothers with poorly controlled diabetes mellitus. The high circulating levels of glucose in the mother transfer to the fetus and stimulate the fetal pancreas to produce insulin. In turn, the high blood levels of insulin in the fetus stimulate overgrowth and fat deposition. Insulin-like growth factors, IGF1 and IGFII, interact with insulin to promote growth of specific tissues such as liver, bones, and adipose tissue, while growth hormone has little effect on fetal body weight and is more important for postnatal growth.

Thyroid hormones are important regulators of fetal growth and the development of the skeletomuscular system, pancreas, brain, and skin. The actions of the thyroid hormones are mediated, in part, by changes in rates of oxygen consumption and oxidative metabolism, and therefore, the energy available for growth. Leptin may also have a role in the control of growth and development of specific fetal tissues, including the pancreas, brain and adipose tissue.

Glucocorticoids, such as cortisol, impair fetal growth in suboptimal intrauterine conditions, such as hypoxia and under-nutrition. These hormones are key physiological signals to suppress general body growth and to divert energy resources to important organs during stressful situations. In addition, glucocorticoids induce a switch in cell processes from proliferation to differentiation in several fetal tissues, which contributes to the normal decline in fetal growth rate near term. Over this period, glucocorticoids promote maturation of a variety of fetal organs in preparation for birth.

Importance of Normal Fetal Growth

The control of fetal growth has important consequences for the short term and longer life-time health of the individual. Neonatal mortality and morbidity is closely related to birth weight, with higher rates associated with the extreme range of birth weight (Basso et al., 2006; Fig. 7). A study in the USA examined the rates of neonatal death, within 28 days of birth, in relation to birth weight in singleton infants born between 1995 and 2000. When all live births were considered, the overall neonatal mortality rate was 38 per 10,000 births with particularly high rates in the smallest, often preterm, infants. The mortality rate was reduced to 8 per 10,000 live births when data from term infants only were assessed, although the relationship between mortality rate and birth weight was maintained (Fig. 7). A number of confounding factors may contribute to the increased risk of death in smaller babies: for example, maternal smoking causes intrauterine growth restriction and increases neonatal mortality by 30% (Basso et al., 2006). Overgrown babies, often born to diabetic mothers, are also at greater risk of neonatal death, in part as a result of obstructed and prolonged labor, and postnatal complications caused by neonatal hypoglycemia and respiratory distress syndrome.

Table 2 Effects of manipulation of hormones on fetal and placental growth

Hormone	Manipulation	Procedure	Species	Weight (% control)		Specific tissue effects
				Fetus	Placenta	
Insulin	Deficiency	Diabetogenic drug treatment	Sheep, monkey	80–85	—	Bone
		Fetal pancreatectomy	Sheep	70	100–110	Liver, spleen, brain
		Insulin gene deletion	Mouse	80	—	Pancreas
		Insulin receptor gene deletion	Mouse	90	100	Liver
		Pancreatic agenesis or insulin receptor defect	Human	50–80	—	
	Overexposure	Fetal insulin treatment	Sheep	100–120	100	Fat
			Monkey	135	—	Fat
IGFI	Deficiency	Maternal diabetes	Human	130	—	Fat
		Igf1 gene deletion	Mouse	60	100	Bone, skeletal muscle
		Igf1 gene defect	Human	50	80	Brain, auditory system
		Igf1r gene deletion	Mouse	45	100	Bone, skin, respiratory muscles
		Igf1r gene defect	Human	50–80	—	Bone, brain
	Overexposure	Fetal IGFI treatment	Sheep	100	100	Liver, lungs, heart, kidney, adrenal gland
IGFII	Deficiency	Igf2 gene deletion	Mouse	60	55	Bone, skeletal muscles
	Overexposure	Igf2 gene expression	Mouse	136	125	Pancreas
		Igf2r gene deletion	Mouse	140	140	Liver, skeletal muscle
		Beckwith–Wiedemann syndrome	Human	150	—	Liver, skeletal muscle
Glucocorticoids	Deficiency	Fetal adrenalectomy	Sheep	115	100	Liver, lungs, gut
	Overexposure	Maternal glucocorticoid treatment	Sheep, monkey, mouse	80–90	65–93	Brain, liver, lungs, heart
			Guinea-pig	84	—	Brain, liver
			Human	85	—	Lungs, gut
		Fetal glucocorticoid treatment	Sheep	80–100	100	Liver, lungs, gut
		Inhibition of placental 11 β -HSD2	Rat	88	—	
Thyroid hormones	Deficiency	11 β -HSD2 gene deletion	Mouse	84	90	
		Deletion of thyroid hormone receptor genes (TR α 1 and β)	Mouse	90	—	
		Fetal thyroidectomy	Sheep	70–80	100	Bone, skeletal muscle, liver, kidneys, heart, fat, pancreas, brain, nervous system
	Overexposure	Fetal thyroxine treatment	Sheep	100	—	Liver, heart
Leptin	Deficiency	Leptin gene deletion	Mouse	100	—	Brain
	Overexposure	Leptin receptor deletion	Mouse	106	100	
		Fetal leptin treatment	Sheep	100	100	Liver, fat, adrenal gland

Size at birth is also an important determinant of health in later life. The epidemiologist, Professor David Barker, and his colleagues at the University of Southampton examined the medical records of around 16,000 men and women born in Hertfordshire, UK between 1911 and 1930. Midwives at the time recorded birth weights and body proportions, and the mortality and morbidity statistics of these individuals were traced 50–70 years later. These studies identified an inverse relationship between birth weight and the incidence of death from cardiovascular disease (Barker, 1997; Fig. 8). For both sexes, the standardized mortality ratio for cardiovascular disease, which included coronary heart disease and stroke, was greatest in the individuals who were smallest at birth. This association between birth weight and adult mortality was continuous across the normal range of birth weights and was also independent of other known risk factors for cardiovascular disease; multiple, premature or severely growth-retarded babies were not included in the data analysis. Other risk factors such as smoking, alcohol intake, adult obesity, and social class were, however, additive to the effects of birth weight.

Fig. 8 Relationship between birth weight and risk of death from cardiovascular disease in men and women aged < 65 years. Redrawn from Barker, D.J. (1997). *Mothers, babies and disease in later life*. London: BMJ Publishing Group.

A number of conditions that predispose to cardiovascular disease have also been associated with low birth weight. Individuals that were small at birth have a higher incidence of hypertension, hyperlipidemia, glucose intolerance, and insulin resistance in adulthood. Further epidemiological studies have demonstrated that the relationship is reverse-J-shaped where large babies born to diabetic mothers are also at greater risk of cardiovascular disease and type II diabetes. Therefore, the intrauterine environment has an important role in programming adult pathophysiology, a phenomenon known as the developmental origins of adult disease (Gluckman and Hanson, 2006). Research is on-going to understand the mechanisms by which a suboptimal intrauterine environment, associated with abnormal patterns of fetal growth, leads to long-term consequences for adult health.

Amniotic Fluid

Ron Beloosesky, Rambam Medical Center at the Technion Faculty of Medicine, Haifa, Israel
Michael G Ross, Harbor-UCLA Medical Center, Torrance, CA, United States

© 2018 Elsevier Inc. All rights reserved.

Amniotic fluid (AF) is essential for normal human fetal growth and development. The AF that surrounds the fetus serves as protection from mechanical trauma, and its anti-bacterial properties aid in maintaining a sterile intrauterine environment. Adequate AF volume (AFV) is necessary for normal development of both the lungs and the limbs. AF includes fetal cells and metabolic by-products, which allows access for fetal diagnosis more often than any other gestational tissue. The first amniocentesis was first performed in 1956 for fetal diagnosis (i.e., sex determination) ([Fuchs and Riis, 1956](#)).

Volume of AF

In the first trimester, the amniotic cavity is surrounded by the fluid-filled exocoelomic cavity and does not contact the placenta or decidua ([Calvo et al., 2002](#)). At this early gestational period the function of the AF is uncertain, as exchange of molecules between mother and fetus involves the exocoelomic fluid. As pregnancy progress the exocoelomic cavity progressively obliterates, and by the end of the first trimester the amniotic cavity is the only significant deposit of extra-fetal fluid. Measurement of AF volumes in the first half of pregnancy demonstrate logarithmical volume increases of AF ([Smith, 1971](#)).

The earliest estimations of AF volume were done during the latter two thirds of human pregnancies through the use of dye dilution techniques ([Geirsson et al., 1984](#)). Findings from these original quantitative findings have been supported by semiquantitative measurements of AF volume performed with ultrasound ([Geirsson et al., 1984](#); [Rolo et al., 2010](#); [Brace et al., 1989](#)). Both of these methods demonstrate a progressive increase in AF volume between 10 and 30 weeks of gestation. AF volume increases from less than 10 mL at 8 weeks ([Smith, 1971](#)) to 630 mL at 22 weeks and reaches 770 mL at 28 weeks' gestation ([Brace et al., 1989](#)), after which the increase slows, AF volume remains unchanged until 36–38 weeks. AF volume decreases sharply as pregnancy proceeds past the due date, averaging 515 mL at 41 weeks. Subsequently, there is a 33% decline in AF volume per week ([Gadd, 1966](#); [Beischer et al., 1969](#); [Queenan et al., 1968](#)), in accordance with the increased incidence of oligohydramnios in post-term gestations. The complex mechanisms that induce these AF volume alterations throughout gestation are not fully elucidated, though are likely attributable to changes in fluid production and resorption (see below).

In pathologic states, the volume of AF may be dramatically altered. Reduced fluid (oligohydramnios) may be near zero while excessive AF volume (polyhydramnios) may total many liters. The normal processes for production and resorption of AF may be affected by fetal anatomic abnormalities such as renal agenesis or esophageal atresia, leading to abnormal AF volumes. Acute or transient changes such as fetal anemia or maternal dehydration may alter AF production/resorption and therefore AF volume. AF volume abnormalities may also occur without apparent cause, though clinically recognized abnormalities of AF volume may be associated with poorer perinatal outcomes ([Chamberlain et al., 1984](#); [Gumus et al., 2007](#); [Volante et al., 2004](#); [Locatelli et al., 2004a](#)).

Production and Composition of AF

In the first trimester AF is isotonic with maternal or fetal plasma ([Campbell et al., 1992](#)) but contains minimal protein. AF demonstrates an extremely low oxygen tension and an increased concentration of sugar alcohols, the product of anaerobic metabolism ([Jauniaux et al., 2005](#)). In the second half of pregnancy, the urine produced by the human fetus is the major component of AF, causing the AF composition to diverge from that of serum. AF osmolality decreases with advancing gestation by 20–30 mOsm/kg to levels approximately 85%–90% of maternal serum osmolality ([Gillibrand, 1969](#)). While, AF urea, creatinine, and uric acid increase, the AF concentrations of urinary byproducts are two to three times higher than in fetal plasma ([Gillibrand, 1969](#)).

The early AF is thought to arise as a transudate of plasma, either from mother across the uterine decidua or the placenta surface or from the fetus through nonkeratinized fetal skin or both; however, the actual mechanism is unknown ([Faber et al., 1973](#)). AF production and resorption have been studied extensively in the second half of pregnancy, primarily in the sheep model. Findings suggest that the entire volume of AF turns over on a daily basis ([Gitlin et al., 1972](#)), representing a highly dynamic system. AF volume is influenced by a complex interplay of absorptive and productive mechanisms ([Seeds, 1980](#)), which act to maintain a physiologically normal volume, suggesting that they may be regulated to normalize AF volume in pathologic conditions.

There appear to be two major sources for both AF production and clearance near term: Production: fetal urine and fetal lung liquid. Clearance: fetal swallowing and intramembranous pathway. Smaller contributors may arise from flow across fetal skin, secretions from the fetal oral-nasal cavities, transudation across the umbilical cord and clearance by transmembranous pathway.

Intramembranous flow refers to water flow from the amniotic cavity to fetal vasculature, whereas transmembranous flow refers to water and solute exchange between AF and maternal blood across the decidua and myometrium ([Brace, 1997](#)). Transmembranous water and solute fluxes are immeasurably small, although these exchanges were once considered major contributors to AFV and composition. Both the intramembranous and transmembranous pathways permit flow of water and solutes in opposite

directions (i.e., osmotic flow of water and diffusion of solutes), while the other pathways only allow flow of water and solutes in the same direction (i.e., bulk flow) (Brace, 1997). Except for fetal metabolic water production, AF ultimately derives from water flow across the placenta from mother to fetus. Thus, alterations in maternal hydration can result in changes in AFV, presumably due to changes in transplacental water flow (Hanson et al., 1997; Ross et al., 1996).

Daily fetal urine excretion and fetal swallowing are the best-described processes for AF production and clearance. However, there remain major differences in the magnitude of current estimates of human fetal urine production (Wladimiroff and Campbell, 1974; Rabinowitz et al., 1989; Hedriana and Moore, 1994). We feel the best estimates of daily amniotic volume flows in the near term fetus are (Brace and Ross, 1998)

- Fetal urine production—800–1200 mL/day
- Fetal lung liquid secretion—170 mL/day
- Fetal swallowing—500–1000 mL/day
- Intramembranous flow—200–400 mL/day
- Oral-nasal secretions—25 mL/day
- Transmembranous flow—10 mL/day

These values are experimentally derived, in many cases using animal models.

Polyhydramnios

Polyhydramnios (also known as hydramnios) refers to an excessive volume of AF. Polyhydramnios has been associated with an increased risk of adverse pregnancy outcomes, including fetal anomalies, preterm birth and placental abruption (Golan et al., 1994; Many et al., 1995; Smith et al., 1992). Polyhydramnios should be suspected clinically when uterine size is large for gestational age. The diagnosis is made prenatally by ultrasound examination. The increase in AFV (AFV) in most cases is asymptomatic. However, the gravida may experience shortness of breath, uterine contractions or irritability, and abdominal discomfort when uterine distention is severe.

In a general obstetric population the incidence of polyhydramnios ranges from 1% to 2% (Hill et al., 1987; Dashe et al., 2002; Thompson et al., 1998; Biggio et al., 1999; Pri-Paz et al., 2012). Reported rates are influenced by variations in diagnostic criteria, subjective vs. quantitative assessments, the population studied (low or high risk) and the gestational age (preterm, term, or postterm) at examination. In one series of 93,332 singleton pregnancies, polyhydramnios was diagnosed during antepartum sonography in 708 pregnancies (0.7%); mild, moderate, and severe disease occurred in 66%, 22%, and 12% of cases, respectively (Dashe et al., 2002).

Etiology

Relatively minor decrease in fetal swallowing or increase in daily fetal urine production can result in a marked increase in AFV (Harding et al., 1984; Pritchard, 1965, 1966). Fetal structural anomalies commonly associated with polyhydramnios are those that interfere with fetal swallowing and/or absorption of fluid (Ben-Chetrit et al., 1990; Stoll et al., 1991). Decreased swallowing may be due to a primary gastrointestinal obstruction (e.g., duodenal, esophageal, or intestinal atresia), neuromuscular disorders (e.g., anencephaly), or to secondary obstruction of the gastrointestinal tract (e.g., massive unilateral dysplastic kidneys).

Fetal anomalies (often associated with an underlying genetic abnormality or syndrome) are the most common cause of severe polyhydramnios, while factors such as maternal diabetes are more often associated with milder cases. In one series of 272 singleton pregnancies with polyhydramnios, approximately 40% were considered idiopathic, one-third were associated with a congenital anomaly and one-quarter were associated with maternal diabetes (Abele et al., 2012). In up to 25% of cases considered idiopathic prenatally, an abnormality is diagnosed postdelivery (Abele et al., 2012; Dorleijn et al., 2009; Touboul et al., 2007, 2009). Neuromuscular disorders, Bartter syndrome, fetal infection and anemia, account for some of these cases and should be considered in the differential diagnosis. In a retrospective observational study of 294 singleton pregnancies with polyhydramnios only two patients tested positive for parvovirus infection and only one for toxoplasmosis infection (Pasquini et al., 2016). Among these patients, 72% were diagnosed with idiopathic polyhydramnios, 13% with maternal diabetes, 5% with fetal obstructive gastrointestinal lesions, 0.3% with Rhesus isoimmunization, and 1% with chromosomal abnormalities or genetic syndromes.

When occurring with fetal growth restriction, polyhydramnios is suggestive of trisomy 18 or 21.

Increased urine production may occur in high fetal cardiac output states (e.g., fetal anemia due to alloimmunization, fetomaternal hemorrhage, alpha-thalassemia, parvovirus infection, glucose-6-phosphatase deficiency) or, rarely, from entities such as fetal Bartter syndrome (Sieck and Ohlsson, 1984).

In monochorionic multiple gestation, polyhydramnios/oligohydramnios sequence is diagnostic of twin–twin transfusion syndrome (TTTS).

The mechanism for polyhydramnios in cases of maternal diabetes is unclear. Fetal polyuria due to hyperglycemia is one likely etiology, and is supported by the observation that polyhydramnios is often associated with high maternal glycated hemoglobin (A1C) levels and fetal macrosomia (Vink et al., 2006; Idris et al., 2010).

Clinical Significance

Many idiopathic cases resolve spontaneously, especially if mild (Golan et al., 1994; Odibo et al., 2016). However, polyhydramnios has been associated with an increased risk of several adverse outcomes in addition to the poor outcomes related to the associated morphologic abnormalities (Ross and Brace, 2001; Karahanoglu et al., 2016; Wiegand et al., 2016)

- Preterm labor, premature rupture of membranes (PROM), preterm delivery
- Maternal respiratory compromise
- Macrosomia
- Fetal malposition
- Abruptio upon rupture of membranes
- Umbilical cord prolapse
- Postpartum uterine atony

Fetal death risk in nonanomalous pregnancies affected by polyhydramnios is increased compared with normal AF pregnancies at each gestational age, with the greatest increase at term (adjusted odds ratio 5.5, 95% CI 4.1–7.6) (Pilliod et al., 2015). Mortality and morbidity increases with increasing severity of polyhydramnios in some, but not all, studies. The combination of polyhydramnios and small for gestational age fetus has a particularly poor prognosis due to the high prevalence of fetal structural and chromosomal abnormalities in this setting (Sickler et al., 1997). Neonatal outcomes associated with idiopathic polyhydramnios include an increased incidence of low 5-min Apgar score, newborn resuscitation, transient tachypnea of the newborn, ventilator requirement, admission to neonatal intensive care unit, hypoglycemia, jaundice and structural anomalies.

Diagnosis

Polyhydramnios diagnosis is based upon sonographic visualization of increased AFV. A 2014 consensus panel at a fetal imaging workshop suggested the following thresholds for polyhydramnios (Reddy et al., 2014).

- Single deepest pocket ≥ 8 cm
- AF index (AFI) ≥ 24 cm

Qualitative impression of mild, moderate, or severe polyhydramnios should be followed by a quantitative measurement, such as the AFI or single deepest pocket (Table 1). Quantitative approaches are standardized and provide a measurement that can be compared over serial examinations, even if sensitivity and positive predictive value (PPV) are low.

Invasive measurement of AFV is not used clinically. If an invasive method such as dye dilution is performed, polyhydramnios is defined as AFV more than two standard deviations above normal for the gestational age. At 34 weeks of gestation, this would be an AFV > 2200 mL (Brace, 1995). There are few large studies comparing the various methods of AF assessment in women with polyhydramnios against a gold standard (i.e., dye dilution) (Magann et al., 2000; Barnhard et al., 1995). One such study compared AFI 25 cm to a dye standard for diagnosis of polyhydramnios, and sensitivity, specificity, and PPVs and negative predictive values (NPVs) were 30%, 98%, 57%, and 93%, respectively (Chauhan et al., 1997).

Sonographic evaluation should be performed for fetal anomalies or fetal hydrops. The likelihood of identifying the etiology of polyhydramnios correlates with severity of fluid accumulation. In one series, an etiology was determined in only 17% of mild polyhydramnios, but in 91% of those with moderate or severe AF accumulation (Hill et al., 1987). In another study, the frequency of an anomalous infant with mild, moderate, and severe polyhydramnios was 8%, 12%, and 31%, respectively (Dashe et al., 2002). Eighty percent of anomalous infants with polyhydramnios were detected prenatally. The prevalence of aneuploidy in anomalous fetuses with polyhydramnios was reported to be 10% (Dashe et al., 2002). However, studies using microarray for genetic analysis have reported nearly 10% of fetuses with AF index (AFI) > 25 cm had genetic abnormalities while demonstrating a normal detailed fetal ultrasound examination (Allaf et al., 2015; Lamouroux et al., 2016; Boito et al., 2016). The abnormalities included trisomy 18 (10 cases), trisomy 21 (10 cases, sex chromosome aneuploidies (8 cases), tetrasomy 12 p (2 cases), microdeletions/microduplications (15 cases), and uniparental disomy 14 (1 case).

Congenital infection may be associated with fetal abnormalities (e.g., hydrops, growth restriction, cerebral ventriculomegaly, hepatosplenomegaly, intracranial and intraabdominal calcifications, ascites, and hyperechogenic fetal bowel). In the absence of maternal signs and symptoms or fetal findings, congenital infection is an unlikely cause of isolated polyhydramnios (Pasquini et al., 2016; Fayyaz and Rafi, 2012).

Table 1 Criteria for mild, moderate, and severe polyhydramnios

	<i>Mild</i>	<i>Moderate</i>	<i>Severe</i>
Single deepest pocket	8–11.9 cm	12–15.9 cm	≥ 16 cm
Amniotic fluid index	25–30 cm	30.1–35 cm	> 35 cm

Oligohydramnios

Oligohydramnios (reduced AFV) is usually diagnosed by ultrasound examination and may be described qualitatively (e.g., normal, reduced) or quantitatively (e.g., $AFI \leq 5$). Oligohydramnios may inhibit normal fetal movement and growth and can lead to umbilical cord compression, fetal deformation and death. The incidence of oligohydramnios is influenced by variations in diagnostic criteria, the gestational age at the time of the ultrasound examination (preterm, term, or postterm) and the population studied (low or high risk). In one large study of 3050 uncomplicated pregnancies with singleton non-anomalous fetuses between 40 and 41 6/7 weeks of gestation, oligohydramnios (defined as $AFI \leq 5$ cm) was observed in 11% (Locatelli et al., 2004b). The incidence is high in laboring women, largely due to rupture of fetal membranes during or just before labor (Rutherford et al., 1987; Ahn et al., 1989; Mercer et al., 1984).

Etiology

The etiologies of oligohydramnios vary according to the trimester in which they are diagnosed and the severity. The majority of women with oligohydramnios or borderline/low normal AFV have no identifiable cause. Conditions commonly associated with oligohydramnios are listed in Table 2. Homeostatic mechanisms, such as intramembranous absorption (transfer of AF across the amnion into the fetal circulation) serve to maintain AFV. These mechanisms are more successful in limiting excess fluid volume than in preventing reduced fluid volume. As an example, only two-thirds of fetuses with duodenal or proximal jejunal atresia and half of fetuses with esophageal atresia, develop polyhydramnios (Underwood et al., 2005) whereas renal agenesis invariably results in oligohydramnios.

The etiology of oligohydramnios in the first trimester is often unclear. Reduced AF prior to 10 weeks of gestation is rare because gestational sac fluid is primarily derived from the fetal surface of the placenta, transamniotic flow from the maternal compartment, and secretions from the surface of the body of the embryo. Criteria suggested for determining reduced AF at this gestational age have included a difference between mean gestational sac size and crown-rump length of less than 5 mm or a mean gestational sac diameter/crown-rump length ratio outside the normal range for gestational age (Bromley et al., 1991; Tadmor et al., 1994).

In the second trimester fetal urine begins to enter the amniotic sac and the fetus begins to swallow AF. Therefore, disorders related to the fetal renal/urinary system play a prominent role in the etiology of oligohydramnios (Table 3). Placental and maternal factors, as well as rupture of the fetal membranes, are also common causes of oligohydramnios in the second trimester.

The etiologies of mid-trimester oligohydramnios were illustrated in a series of 128 fetuses first noted to have severe oligohydramnios/anhydramnios at 13–24 weeks of gestation (Shipp et al., 1996a). The following etiologies were observed: fetal anomaly (51%), preterm premature rupture of membranes (PPROM) (34%), placental abruption (7%), fetal growth restriction (5%), and unknown (4%). Among the 65 anomalous fetuses, six were aneuploid. An elevated maternal serum alpha fetoprotein (MSAFP) concentration has also been linked to second trimester oligohydramnios, with or without an anomalous fetus. This combination carries an extremely poor prognosis: preterm delivery, fetal growth restriction, fetal death, neonatal death (Dyer et al., 1987). Oligohydramnios associated with an elevated MSAFP level may be caused by fetal membrane or placental damage, with leakage of AF or fetal blood into the maternal circulation (Los et al., 1992).

Oligohydramnios following amniocentesis appears to have a better prognosis. The membranes often “reseal” with reaccumulation of AF and normal pregnancy outcome.

Oligohydramnios first diagnosed in the third trimester is often associated with premature rupture of membranes or with uteroplacental insufficiency. Fetal growth restriction is frequently accompanied to oligohydramnios related to uteroplacental

Table 2 Causes of oligohydramnios

<i>Maternal</i>
Medical or obstetrical conditions associated with uteroplacental insufficiency (e.g., preeclampsia, chronic hypertension, collagen vascular disease, nephropathy, thrombophilia)
Medications (e.g., angiotensin converting enzyme inhibitors, prostaglandin synthetase inhibitors, trastuzumab)
<i>Placental</i>
Abruption
Twin to twin transfusion (i.e., twin polyhydramnios–oligohydramnios sequence)
Placental thrombosis or infarction
<i>Fetal</i>
Chromosomal abnormalities
Congenital abnormalities, especially those associated with impaired urine production
Growth restriction
Demise
Postterm pregnancy
Ruptured fetal membranes
<i>Idiopathic</i>

Table 3 Type and frequency of congenital anomalies associated with oligohydramnios in a literature review

Type	Number of cases (percent)
Renal	94 (65)
Multiple	17 (12)
Aneuploidy	12 (8)
Central nervous system	7 (5)
Skeletal system	5 (4)
Cardiovascular system	4 (3)
Other	6 (4)
Total	145

Adapted from Hill, LM. Clin Obstet Gynecol. 1997; 40:314.

insufficiency. Postterm AFV normally decreases often resulting in oligohydramnios, while many cases of third trimester oligohydramnios are idiopathic. There may be an association between oligohydramnios and pregnancy during the summer season, likely related to suboptimal maternal hydration in hot weather (Feldman et al., 2009). Mechanisms of isolated oligohydramnios also may include alterations in the expression of water pores (aquaporin 1, aquaporin 3) in fetal membranes and placenta (Zhu et al., 2009).

Oligohydramnios may be first suspected because the uterine size is less than expected for gestational age. Clinical diagnosis is based on the finding of decreased AF on ultrasound examination, with either subjective or objective ultrasound criteria. Although use of objective criterion is generally preferable (AF index ≤ 5 cm; single deepest pocket < 2 cm), subjective suspicion of AFV by experienced examiners has similar sensitivity for diagnosing reduced AFV.

AFI 5th %ile averages approximately 7 cm throughout gestation, an AFI ≤ 5 cm is greater than two standard deviations below the mean value (Magann et al., 1997; Moore and Cayle, 1990). For diagnosis of oligohydramnios in a multiple gestation, single deepest vertical pocket is utilized (< 2 cm).

Methods of Increasing AFV

No treatment of oligohydramnios has been proven to be effective long-term. Although, short-term improvement of AFV is possible and may be used under certain circumstances, such as when a fetal anatomic survey is needed.

Amnioinfusion can increase AFV temporarily. Transabdominal amnioinfusion of approximately 200 mL of saline under ultrasound guidance can provide better visualization of fetal anatomy.

Maternal hydration: In isolated oligohydramnios with no indication for delivery oral hydration with one to two liters of water can increase AFV transiently. Maternal hydration is easier and safer than intravenous fluid administration or amnioinfusion. The mechanism of hydration is likely via reduction of maternal plasma osmolality and sodium concentration, resulting in osmotically driven maternal to fetal water flux. A recent review found that maternal hydration was most effective in pregnancies with isolated oligohydramnios and that hypotonic solutions were more effective than isotonic fluids (Phelan et al., 1987).

Prognosis and Management

The prognosis of oligohydramnios depends on the severity, etiology, gestational age at onset, and duration of oligohydramnios. In the first trimester, oligohydramnios is an ominous finding, associated with a high incidence of spontaneous abortion. In the second trimester, pregnancies with borderline/low normal AFV generally have a good prognosis (Mercer et al., 1984) while severe oligohydramnios often ends in fetal or neonatal demise (Gizzo et al., 2015). In a series of 128 fetuses first noted to have oligohydramnios at 13–24 weeks of gestation, survival occurred in 20% of fetuses with PPROM, abruption, and idiopathic cases, 1.5% in fetuses with congenital anomalies, and none in fetuses with fetal growth restriction (Gizzo et al., 2015). Preterm delivery, spontaneous or indicated, occurs in $> 50\%$ of cases (Mercer et al., 1984; Dyer et al., 1987).

In the third trimester, some (Rutherford et al., 1987) but not all (Shipp et al., 1996b) studies have demonstrated an inverse relationship between AFV and the incidence of adverse pregnancy outcome. Adverse outcomes are related to umbilical cord compression, uteroplacental insufficiency, and meconium aspiration.

Idiopathic isolated oligohydramnios at term appears to have a better prognosis. In a retrospective cohort study (Ashwal et al., 2014), no increased risk for a composite adverse outcome were demonstrated when pregnancies complicated by thrombophilia, diabetes, hypertension, fetal growth restriction, or chromosomal/structural abnormalities were excluded.

Duration of oligohydramnios is also a prognostic factor. Idiopathic oligohydramnios diagnosed at an earlier gestational age are at risk for adverse perinatal outcomes compared with those presenting later in gestation (Shipp et al., 1996a). Given the potential for adverse outcome, patients are often delivered if at or near term, while preterm pregnancies may be hospitalized for frequent assessments or managed as outpatients (Clark et al., 1989; Carroll and Bruner, 2000).

Fetal–Placental–Fetal Membrane Development

Human fertilization begins when a male gamete or sperm fuses with the female gamete or oocyte, generating a unique, and diploid chromosome aggregation called the zygote. The zygote undergoes mitotic divisions to increase the number of embryonic cells and the newly formed morula migrates into the uterus and begins to fill with fluid to form a blastocyst. The telomere (DNA structure that protects chromosomal integrity by forming guanine-rich caps) length, a measure of the biologic age of a cell, and telomerase (an enzyme that maintains telomere length) have also been shown to peak at the blastocyst stage, possibly setting the biologic age of all fetal-derived cells. The blastocyst divides into two parts: an outer layer, the trophoblast, which will form the embryonic part of the placenta, and a group of centrally located blastomeres, the embryoblast, which will develop into an embryo (Watson, 1992).

Blastocyst implantation in the uterine endometrium coincides with the development of a small space in the embryoblast that will form the amniotic cavity. Morphologic changes in the embryoblast result in the formation of the embryonic disc, a bilaminar plate formed by two layers: the epiblast, which constitutes the floor of the amniotic cavity, and the hypoblast, which together with the exocoelomic membrane forms the primitive yolk sac. Isolated cavities or gaps that occur in the syncytiotrophoblast are filled with a mixture of maternal blood and cell debris. Oxygen and maternal blood nutrients present in these gaps become available for embryo development (Fig. 1A). The placenta is made up of fetal-derived tissues through which the fetus derives its nutritional support, maintains its immunological tolerance, and receives and produces regulatory hormones (e.g., progesterone, estrogen,

corticotropin-releasing hormone (CRH), human chorionic gonadotropin (hCG), etc.) (Magon and Kumar, 2012) that are vital for pregnancy maintenance. Blood vessels present in the placenta allow the entry and exit of maternal blood, establishing the uteroplacental circulation. Blood circulation is connected to the growing fetus through the umbilical cord which is comprised of two arteries and a vein surrounded by connective tissue (Wharton's jelly) and covered by epithelial cells (Fig. 1B) to help remove CO₂ and other metabolic wastes. Connected to the fetal side of the placenta are the fetal membranes (amniochorion), which surround and line the intrauterine cavity (Fig. 1C). Fully formed amniochorion comprises amnion and chorion connected by an extracellular matrix region. The exact development process of amnion and chorion and their demarcation period into amniochorionic membranes as a unit are still unclear. The development of amnion and chorion begins with embryogenesis, although they do not participate directly in the formation of the embryo or fetus. Like the fetus, early growth of the amnion and chorion layers is rapid and independent of each other. The formation of amniochorion as a unit structure is completed between the 13th and 15th weeks of gestation (Fox, 1997). The growth and development of amniochorion correlate with fetal growth with a longevity of 40 weeks (term gestation period). The telomere length, as mentioned above, of these fetal-derived intrauterine structures has been shown to decrease from ~18 kb (22 weeks gestation) to ~7 kb (41 weeks gestation) during a 19-week period, suggesting (Menon et al., 2012) that all the components of the intrauterine cavity biologically age throughout pregnancy.

Amniochorion Membrane Organization

The amniochorion membrane (fetal or placental membrane) is one of the vital compartments of intrauterine cavity, performing mechanical, immune, and endocrine functions throughout gestation. The avascular fetal membranes are made up of a cuboidal amnion epithelium, a multilayered extracellular matrix (ECM) containing mesenchymal cells, and the chorion that connects to the decidua and myometrium (Fig. 1C), where the latter is maternal tissues. The fetal-derived components of the fetal membranes contain two primary layers: the amnion membrane (AM), consisting of amnion epithelial cells through half of the spongy layer, and the chorion membrane, which contains the other half of the spongy layer through the chorionic trophoblast cells. Both components include mesenchymal stromal cells (Bryant-Greenwood, 1998). By week 15, the amnion and chorion layers are fully formed and fuse to act as the barrier of the uterine cavity.

Amnion Membrane Components

Amnion Membrane

The AM is made up of an amnion epithelium, supported by basement membrane made of Type IV collagen. Beneath the basement membranes are stromal cells embedded in a collagen-rich ECM (compact, fibroblast, and half of the spongy layer). This section of the fetal membranes bears the most tensile strain and mechanistically keeps the whole fetal membrane intact as the fetus grows and develops. The AM is a source of several biologically active factors involved in tissue regeneration and remodeling, as seen in Table 1 (Litwiniuk and Grzela, 2014). Growth factors promote proliferation, migration, differentiation, and re-epithelialization during gestation. Specifically, epidermal and keratinocyte growth factor stimulates the proliferation and migration of epithelial cells, playing an important role in tissue remodeling (Litwiniuk and Grzela, 2014). In the same way, transforming growth factor beta (TGF- β) regulates cell proliferation, migration, and differentiation, as well as extracellular matrix remodeling. Moreover, TGF- β inhibits ECM degradation by increasing collagen production, suppressing the expression of metalloproteinases and stimulating their tissue inhibitors (Ogawa et al., 2004). It is critical that these processes remain in homeostasis throughout gestation to accommodate the changes associated with pregnancy, specifically fetal growth and increase in volume.

Amnion Epithelium

The amnion epithelial layer, bathed in amniotic fluid, is a single layer of cuboidal cells held together by neighboring cells gap junctions. Stress and stretch exerted on this layer make them undergo constant turnover as epithelial cells shed due to either apoptosis or senescence as the membranes age. Amnion cells secrete collagen Types IV and glycoproteins to form the basement membrane on their basal side. This creates a junction and allows communication between the amnion and ECM.

Amnion epithelial cells express a variety of surface markers that include pluripotent stem cells, mesenchymal, hematopoietic, and epithelial markers (Table 2). Current research from our lab shows that amnion epithelial cells and amnion mesenchymal cells co-express both epithelial and mesenchymal intermediate filaments (Cytokeratin-18 and Vimentin), highlighting the intermediate state (metastate) of these cells (Fig. 2), regardless of gestational age. This is indicative of constant turnover of these cells and remodeling of membranes. Regulated inflammatory activity by amnion epithelial cells, with the expression of antiinflammatory proteins like TGF- β , IL-10, IL-1 receptor-agonist and tissue inhibitors of matrix collagen degrading enzymes metalloproteinases (García-Castro et al., 2015), along with pro-inflammatory mediators, promote tissue remodeling throughout gestation.

Extracellular Matrix

In general, the AM ECM is comprised of many layers each with a unique composition of collagens and elastin. Collagen is a major component of the fetal membranes ECM. Elastin and microfibrils give the membranes their viscoelastic properties and allow them

Table 2 Characteristics of amnion epithelial cells

<i>Name of product</i>	<i>Preservation methods</i>	<i>Useful properties</i>
Grafix	Cryopreserved placental allografts	Increase wound closure, shorten healing time, lead to fewer adverse events, and less wound related infection
NEOX Wound Allograft	Cryopreserved placental allografts and umbilical cord	Promote complete epithelialization and speed up wound recovery time
EpiFix	Dehydrated fetal membranes	Contribute to complete wound closure uses less graft material, and delivers a lower median cost to treatment providers
AmnioExcel	Dehydrated fetal membranes	Significant increase in wound closure and a more rapid recovery

Fig. 2 Amnion epithelial cells and amnion mesenchymal cells co-express epithelial and mesenchymal factors. Confocal immunofluorescence images of amnion epithelial cells (AEC) and amnion mesenchymal cells (AMC) showing the co-expression of cytokeratin-18 and vimentin. In the AECs, cytokeratin-18 is *green* and vimentin is *pink*, while in the AMCs cytokeratin-18 is *red* and vimentin is *green*.

to withstand the stretch and strain associated with fetal growth. Formed by precursor proteins called tropoelastins, elastin forms elastic fibers outside of cells. The cross-linkage of these fibers forms microfibrils, which are abundant in the stromal layers of the AM. Fibronectin, laminins, proteoglycans, hyaluronan, and other types of collagen also play a significant structural and functional role in the development and remodeling of fetal membrane ECM.

Underneath the basement membrane of the amnion epithelium lies the second ECM layer of the AM, the compact layer. This layer is made up of Type 1 and 3 collagens which account for the high tensile strength of AM. Stromal mesenchymal cells secreting Type 1 and 3 collagens create the compact layer and fibroblast layer, forming a fibrous skeleton maintaining amnion integrity (Strauss, 2012). The fibroblast layer connects to the spongy layer made up of proteoglycans, glycoproteins (Strauss, 2012), and Type 3 collagen, producing a spongy meshwork. The reticular layer, made up of fibrillar bundles of collagen, is attached to the spongy layer on its apical side and the chorion pseudo-basement membrane, made of Type 4 collagen, on its basal side.

Amnion Stromal Cells

The amnion ECM layers are filled with amniotic mesenchymal stromal cells, fibroblasts, and small amounts of tissue macrophages (Uchide et al., 2012). These cells can interact with each other, produce inflammatory mediators including enzymes to degrade collagen matrix, and communicate with cellular layers to help with the fetal membrane remodeling. Amniotic mesenchymal cells are characterized morphologically by a small cell body with a round nucleus with a prominent nucleolus. They are long and thin and express various stem cell, mesenchymal, and immune-privileged markers (Huo et al., 2010) (Table 3). Fibroblasts in the amnion ECM are very versatile cells that produce biochemical mediators like growth factors, cytokines, and proteases, and are involved in tissue repair and regeneration (Table 3) (Costa-Almeida et al., 2017). These cells share several characteristics with mesenchymal stem cells (Table 3). Amnion mesenchymal cells and fibroblasts are responsible for making and redistributing ECM components that are critical for cellular and structural support of the fetal membranes throughout gestation.

Chorion Membrane Components

Chorion Membrane

As discussed before, it is thought that the amnion layer is a structural and mechanical barrier of the fetus, whereas the chorion layers prevent amnion degradation and protect the fetus from the maternal immune system. The formation of chorion starts by day 14, when mesenchymal cells, derived from the embryonic disc, spread underneath the inner surface of the cytotrophoblast layer of the implanted blastocyst and form the chorionic sac. The chorion consists of two layers: an outer formed by the trophoblast, and an inner formed by the somatic mesoderm. The trophoblast is made up of an internal layer of cubical cells, named cytotrophoblast, and an external layer of richly nucleated protoplasm devoid of cell boundaries, the syncytiotrophoblast.

Table 3 Characteristics of stromal cells

<i>Tissue type</i>	<i>Categories</i>	<i>Specific name</i>	<i>Abbreviation</i>
Amnion epithelial cells	Pluripotency markers	Sex determining region Y- box 2	SOX2
		Octamer-binding transcription factor 4	4-Oct
	Stem cell markers	NANOG	
		Stage-specific embryonic antigen 3	SSEA-3
		Stage-specific embryonic antigen 4	SSEA-4
		TRA1-60	
	Mesenchymal and hematopoietic markers	TRA1-81	
		Endoglin	CD105
		Thymocyte differentiation antigen 1	Thy-1 or CD90
		Neprilysin	CD10
		Aminopeptidase	CD13
		CD17	
		CD44	
		Integrin beta-1	CD29
		Human leukocyte antigen A	HLA-A
		Human leukocyte antigen B	HLA-B
		Human leukocyte antigen C	HLA-C
	Epithelial markers	N-cadherin	CDH2
		Vimentin	VIM
		E-cadherin	CDH1
		Cytokeritin-18	CK-18
		Cytokeritin-19	CK-19
		Cytokeritin-7	CK-7

The chorion is comprised of multiple layers of cytotrophoblast cells and a stroma that fuses with the amnion in the mature fetal membrane. These cells contain stem cell markers, cluster of differentiation (CD) CD34 and CD45, reinforcing the hematopoietic potential of the chorion. The chorionic membrane also contains more growth factor and more cytokines compared with amniotic membrane. The chorion shows higher levels of adiponectin, fibroblast growth factor, endocrine gland-derived vascular endothelial growth factor, hepatocyte growth factor, insulin-like growth factor-1, platelet-derived growth factor-AA and -BB, tissue inhibitor of metalloproteinase (TIMP)-2 and -4, while the amnion has higher levels of galectin-7, TGF- β 1, and interleukin-1F5 (McQuilling et al., 2017). Besides that, the chorion presents a stronger antibacterial effect than the amnion (Zare-bidaki et al., 2017). These studies reinforce the maternal role of the placenta in protecting the fetus against possible infections.

Summary

From the point of conception, highly unique, pluripotent stem cells that surround the fetus forming the AMs are vital to fetal survival. The amniochorion membranes are composed of multiple cellular and stromal layers containing epithelial and mesenchymal stem cells. These cells are used in a variety of fields, forming organs in vitro, and improving wound healing in clinics. By understanding where these cells come from and what their uses are in other areas, we can get a better idea of how they will act in vivo.

Membrane Properties That Maintain Pregnancy

Factors Maintaining Mechanical Integrity

Recently, it has been shown that progesterone, a pro-gestation hormone constant throughout pregnancy, inhibits signals such as tumor necrosis factor- α , thrombin, TGF- β , or granulocyte-macrophage colony-stimulating factor, which could weaken fetal membrane integrity. Contrary to the use of genomic receptors in maternal uterine tissues, progesterone uses the progesterone receptor membrane component (Feng et al., 2016) (PGRMC) to exert its function in the membranes. This unique ligand-receptor-mediated mechanism highlights progesterone's critical role in ECM homeostasis throughout gestation. The precise mechanism of progesterone- PGRMC mediated signaling is still not fully elucidated. However, this ligand receptor complex exerts a multitude of antiinflammatory properties in in vitro experiments. A decrease in PGRMC during term or preterm labor might contribute to the "functional withdrawal" of progesterone action and shift the balance to a state of inflammation (Zare-bidaki et al., 2017). This is partly facilitated by a constitutive expression of prostaglandin dehydrogenase (PGDH), an enzyme capable of degrading PGs, during gestation to minimize uterotonic functions and keep the uterus quiescent. A reduced functional role of progesterone and reduced expression of PGDH (which will increase bioavailable prostaglandin) may indicate a central role by human fetal membranes at the time of labor, at term or preterm.

Low levels of oxidative stress, especially during membrane remodeling, can help stimulate the small levels of inflammation needed to rebuild and modify the fetal membranes. AM also protects against large amounts of oxidative stress and inflammation through the production of superoxide dismutase, catalase, and expressing antiinflammatory peroxisome proliferator-activated receptor gamma. These factors prevent free radicals from causing DNA, lipid, and protein damage or cause inflammatory mediator activation. Low levels of prostaglandins also localize near sites of injury or infection to increase the levels of inflammation in order to stimulate tissue remodeling.

Role of Microfractures in Membrane Remodeling

Forming a watertight tight seal for the retention of amniotic fluid to protect the inner layers of the fetal membranes is another job of the amnion. Damage to this seal can cause a breakdown of homeostasis, and lead to catastrophic deterioration of the membranes. Temporary loss of cells and matrix collagens is inevitable during growth and remodeling; however, the impact is minimized by remodeling machinery. We have identified sites where such remodeling may occur during gestation, and these sites of fetal membrane remodeling are collectively called microfractures. Microfractures are not necessarily a fracture, but a term that is defined by amnion epithelial cell puckering, basement membrane degradation, collagen matrix degradation, and the development of tunnels with migratory cells. These sites are remodeled by cells and nascent collagen during normal gestation, but under pathological conditions, the persistence of microfractures and a lack of resealing could function as channels for leakage of the amniotic fluid (Fig. 3) (Richardson et al., 2017). We have noticed that the number and morphometric features (height, width, and depth) of microfractures are high in membranes from preterm premature rupture of the membranes (pPROM) and preterm birth compared to preterm births with intact membranes. This suggests that microfractures may serve as a clinical and biomarker for pPROM.

Membranes Contribution to Parturition

Cellular and Biological Regulators of Parturition

The fetal membranes are composed of tissues that are fetal in origin. At the maternal-fetal junction, fetal membranes adhere to the decidualized endometrium and form an immuno-mechanical interface. As mentioned in the opening paragraphs, fetal

Fig. 3 Characteristics of microfractures. (A) Multiphoton autofluorescence microscopy (MPAM) images of amnion epithelial cell puckering above a microfracture. (B) MPAM and second harmonic generation microscopy image of deteriorated basement membrane (*white arrows*) under areas of altered amnion morphology (*puckering*). (C) Term not in labor (TNIL) microfracture processed with IMARIS demonstrating the average depth and width. (E) Term labor microfracture processed with IMARIS, demonstrating deeper microfractures than TNIL.

membranes undergo a telomere-dependent aging coinciding with fetal growth and maturation. We have noticed that telomerase activity decreases in fetal membranes by the late 1st trimester, and it is minimal to negligible in the 2nd and 3rd trimesters. This suggests that fetal membranes are programmed to age naturally and progressively in utero. Aging is mechanistically mediated by molecular and cellular senescence. As membranes reach their longevity at term, aged membranes can initiate signaling of labor and delivery. Fetal membranes play a critical role in coordinating labor with the help of fetal signals of organ maturation. These fetal signals include endothelin, various growth factors, and chemokines, all of which are capable of increasing inflammation and oxidative stress in the uterine tissues, thus accelerating the membrane aging process (Menon, 2016).

Role of Senescence at Term

Senescence is a mechanism of tissue aging that can contribute to molecular, biochemical, and morphological level changes in the membranes. Amnion epithelial cells treated with cigarette smoke extract (CSE), a well-known oxidative stress inducer, leads to DNA damage and stress signaler p38 mitogen-activated protein kinase activation (MAPK). p38MAPK activation has been shown to cause senescence in fetal membranes as well as producing senescence-associated secretory phenotypes (SASPs), a unique group of inflammatory mediators comprising cytokines, chemokines, and various pro-inflammatory markers. SASPs create an environment of sterile inflammation in the fetal membranes. Besides, senescent fetal membranes also cause the release of damage-associated molecular patterns (DAMPs) from aged and oxidatively damaged tissues (Menon et al., 2016). SASPs and DAMPs are paracrine signalers released from fetal membranes and are capable of signaling parturition by propagating their inflammatory functional signals to the maternal side. We postulate that this signal propagation occurs in two different ways: diffusion through (1) microfractures, or (2) exosomes released from fetal membrane cells. Microfractures are higher in number and deeper at term (in vivo). Experimentally, we have shown that labor in in vitro conditions that mimic term labor also cause the increased appearance of microfractures with larger and deeper features. This suggests their relevance in the propagation of parturition signals. Exosomes are 30–150 nm size microvesicles that are capable of carrying contents from the cell of their origin. We have reported that exosomes from oxidatively stressed fetal membrane cells carry active forms of p38MAPK, SASPs, and DAMPs (Sheller et al., 2016). Thus, fetal membranes at term undergo senescence, they deteriorate and produce powerful pro-inflammatory signals that are sent as signals through various channels to convey to the maternal side the readiness of labor and delivery of the fetus.

(parturition). The primary purpose of these signals is to enhance the inflammatory load on the maternal side, a condition that is considered as the effector of labor and delivery.

Mechanical Contributions of Membranes at Term

Throughout gestation, the fetal membranes, layers of collagen extracellular matrix ($\sim 80 \mu\text{m}$) and cells, are responsible for upholding a protective barrier and watertight seal for the fetus and amniotic fluid. Membranes can withhold tensile and mechanical strain due to the elasticity of the AM and the variety of collagen and elastin that comprise the ECM. At term, a combination of programmed biochemical changes associated with senescence and physical stretch of membranes can lead to collagenolysis, leading to tissue damage (Moore et al., 2006). Excessive stretching and mechanical derangements result in the production of cytokines, prostaglandins, and collagenases, a phenomenon that contributes to the sensitization of the myometrium and the onset of uterine contractions (Waldorf et al., 2015). Stretching of membranes can also cause activation of p38MAPK, accelerating senescence and the release of DAMPs, contributing to mechanical changes. Endocrine factors like progesterone have been shown to reduce the weakness of fetal membranes and thus support pregnancy, whereas tumor necrosis factor- α and granulocyte macrophage colony stimulating factor, pro-labor factors prominent during infection or senescence, have been shown to induce fetal membrane weakening.

Membranes Contribution to Preterm Parturition

Diseases Contributed by Membranes

Preterm birth is defined as birth before the 37th week of complete gestation. Preterm labor and delivery can be medically induced or spontaneous. Spontaneous preterm birth can be subdivided into two categories: preceded by preterm labor with intact membranes, or preceded by pPROM. Among spontaneous preterm births, the incidence of preterm full-term is about 60%, and that of pPROM is 30%–40% (Menon, 2008; Beck et al., 2010). The etiologies, pathways, and mechanisms of spontaneous preterm birth and pPROM are still unclear; however, oxidative stress and inflammation arising from a multitude of risk exposures contribute to these syndromes. As our current understanding of the mechanistic events leading to these conditions is unclear, we have postulated novel mechanisms based on our findings on fetal membrane senescence.

Role of Premature Senescence

Fetal membrane senescence and senescence-associated sterile inflammation at term are normal physiologic responses arising due to the longevity of fetal membranes. This longevity coincides with fetal growth and development. However, with premature activation of senescence in response to various preterm birth risk factors, it may become a pathological factor. Similarities between senescence mechanism-associated factors in term labor and pPROM suggest fetal membranes' contribution to both these conditions. Both term and pPROM demonstrate heightened fetal membrane oxidative stress, oxidative stress-induced cellular, and organelle damage (nucleus, mitochondria, endoplasmic reticulum), stress-associated p38MAPK, senescence and SASP. In vitro studies showed that many of these events could be minimized or terminated by p38MAPK inhibitor, confirming a role for this mechanistic process (Dutta et al., 2015). Thus, fetal membrane senescence prematurely at preterm contributes to pathways of preterm birth.

Membrane Matrix Lysis in pPROM

The rupture of fetal membranes is a process involving collagen degradation. Collagen is a major structural component of the membranes, providing the strength to withstand physical stretch. Matrix metalloproteinases (MMPs) are the only enzymes that act to degrade collagen and play a major role in tissue remodeling. MMP types 2 and 9 degrade Type IV collagen, which is found in the basement membrane (Vadillo-Ortega et al., 1995). The activities of MMPs are regulated mainly by specific TIMPs, and a balance between activators and inhibitors controls the activity of MMPs. Reactive oxygen species, inflammation, and infection have been associated with an imbalance in MMP/TIMP activity, causing increased collagenolysis in the amnion cavity, which is directly related to a decrease in the tensile strength of fetal membranes. MMP-9 are increased in the amniotic fluid of women with intrauterine infection. MMP-2 are increased in membranes exposed to LPS in vitro.

Collagenolysis is mediated by various risk factors inducing inflammation (chorioamnionitis) and oxidative stress. These risk factors can cause increased senescence, apoptosis (programmed cell death), and necrotic types of changes in fetal membranes to activate a collagenolytic process predisposing membranes to rupture (Menon and Richardson, 2017).

Membrane Inflammation, Immune Disruption, and Infection in PTB

Intraamniotic inflammation is a major factor associated with preterm birth and pPROM. The fetal membranes can produce inflammation—sterile and/or infectious—that can arise from a multitude of pathologies and contribute to adverse events during pregnancy.

As described before, sterile inflammation is a feature of senescence-associated aging, and this is characterized mostly by the presence of inflammatory biomarkers, growth factors, and matrix-degrading enzymes. Granulocyte-macrophage colony-stimulating factor is increased in the intrauterine cavity in response to oxidative stress-induced fetal cell senescence. This, an inflammatory marker, can reduce fetal membrane structural strength and compromise fetal membrane integrity, causing the rupture (Murtha et al., 2015). On the other hand, the innate immune system plays a key role in regulating the parturition pathway. The host inflammatory response to microbial colonization and/or infection can determine the pregnancy outcome too. Special sentries of the innate immunity, named pattern recognition receptors (PRRs), recognize structurally stable microbial elements, termed pathogen-associated molecular patterns (PAMPs) (Kawasaki and Kawai, 2014). In addition to microbial ligands, PRRs have been shown to respond to endogenous molecules released by tissue or immune cells in response to injury or inflammation, referred to as DAMPs (Piccinini and Midwood, 2010).

Activation of toll-like receptors by specific PAMPs and DAMPs leads to a downstream cascade orchestrated by the transcription factor nuclear factor kappa-light-chain-enhancer of activated B cells (NF- κ B), which results in the production of effector molecules, such as pro-inflammatory cytokines, chemokines, prostaglandins, proteases and other enzymes which can also cause the release of uterotonins to promote preterm parturition.

Another pathway that plays an important role in the processes of human labor and delivery is the activation of AP-1. Differently than the NF- κ B pathway, AP-1 signalization happens through activation of mitogen-activated protein kinases (MAPK). MAPK families play an important role in complex cellular programs like proliferation, differentiation, development, transformation, and apoptosis. At least three MAPK families have been characterized: extracellular signal-regulated kinase (ERK), Jun kinase (JNK/SAPK) and p38 MAPK. MAPK/AP-1 proteins are modulated by growth factors, cytokines, stress, and bacterial infections and play a part in the regulation of both pro- and antiinflammatory cytokines and in the metalloproteinase-9 activity in human fetal membranes (Lappas et al., 2011).

Maternal Factors That Contribute to PTB

There are many socioeconomic, behavioral, and health risks that affect preterm birth rates. Socioeconomic factors include maternal age, race or ethnicity, and socioeconomic and marital status have been shown to affect the timing of parturition. Maternal behaviors can also contribute to this. Women who smoke or take illegal drugs have a higher rate of preterm birth, specifically with ruptured membranes, while women who exercise and maintain a healthy diet have a lower risk. All these factors can contribute to fetal and fetal membrane homeostasis disruption, contributing to preterm birth pathways.

In summary, fetal membranes play a major role in human pregnancy maintenance and their natural aging can contribute to the inflammatory overload associated with labor and delivery.

Beyond Pregnancy: Beneficial Contributions of Fetal Membranes in Organ Regeneration and Tissue Remodeling

Since the early 19th century, physicians and researchers alike have been using either AM or intact fetal membranes for wound repair, as cell-based wound dressings can be beneficial in many settings. Clinical situations presenting in different fields such as diseases of the ocular surface, diabetic wound healing, surgical dehiscence, burns, deep wounds, and leg ulcers all use advanced cell-based wound dressings to induce healing of the epithelial layer (Litwiniuk and Grzela, 2014) (Fig. 4). There are many different forms of commercially available fetal membranes that are both cryopreserved and dehydrated which are useful in various clinical situations due to the abundance of different stimulating factors (Table 4). In obstetrics, the usefulness of fetal membrane ECM is restricted to filling gaps in the membrane to avoid premature rupture of membranes arising from fetal surgery. This lack of application is partly due to the poor understanding of the properties of amnion epithelial cells and other cells in their extracellular matrix.

Due to their epiblast origin, which is the source of all of the germ layers, the amniotic epithelial cells have a wide differentiation capacity. Recent studies have shown that these cells can differentiate into neurogenic epithelial (ectoderm), hepatic (endoderm), adipogenic, myogenic, osteogenic, and cardiac (mesoderm) lineages (Fig. 5A). These studies highlight the usefulness and ease with which amnion cells can act as pluripotent stem cells. The use of these cells in vitro is vital for researchers who are normally faced with other options involving ethical, legal, and religious concerns with the use of embryonic stem cells and the difficulties involved in obtaining stem cells from adult tissue.

Due to these characteristics, amnion mesenchymal cells and fibroblasts with potent stem cell characteristics are often used in wound healing, repair, and differentiation. In the same way as amnion epithelial cells, various studies have reported differentiation of amnion mesenchymal cells into ectoderm (neural), endoderm (pancreatic), hepatogenic, mesoderm (adipogenic) cartilage, osteogenic, and cardiac and trophoblastic lineages (Fig. 5B). The ability of these cells to differentiate into this variety of cell types and lineages under specific tissue/cell culture environments speaks volumes about its pluripotent nature; however, the ability of these cells to transition due to stimulation in vivo has not been addressed.

Many of the uses of AM in the field of wound healing mentioned above also use fetal membrane ECM devoid of amnion cells as a scaffold to promote wound healing. Removal of the amnion epithelial allows the healing tissues' own epithelial cells to colonize the ECM while receiving the beneficial growth factors and cytokines released from the amnion stromal cells.

Fig. 4 Amnion membrane uses in wound healing. (A) In the ophthalmology field, amnion membranes are used to treat conjunctivitis scarring, acute burns, and persistent cornea defects. This cell-based dressing was chosen because of its transparent nature and its Type IV collagen basement membrane that promotes the expansion, migration, and invasion of epithelial progenitor cells. (B) In the endocrinology field, amnion membranes are used for diabetic foot ulcers as well as foot and ankle injuries such as chronic wounds, fasciitis, and tendonitis. Amnion membranes are used in these fields because they promote faster ulcer closure and help the healing of chronic wounds due to secreted factors. (C) and (D) In dermatology, amnion membranes are used for burns and deep wounds because they reduce pain, infection, increase mobility, and promote re-epithelization. (E) In the field of surgery, amnion membranes are used to help seal surgical incisions and close dehiscence due to their ability to promote closer healing of hard-to-heal wounds. (F) Venous leg ulcers, pyoderma gangrenosum, and epidermolysis bullosa are all treated with amnion membranes because they provide granulation in tissue, reduce pain, allow for proper epithelialization, and decrease the ulcer surface area and secretion of the fibrinous slough.

Table 4 Types of amnion membranes used clinically

Tissue type	Categories	Specific name	Abbreviation
Amnion mesenchymal cells	Pluripotency markers	Octamer-binding transcription factor 4	4-Oct
		Hepatocyte nuclear factor	HNF-3 β
	Immune privileged markers	NANOG	
		Neuroectodermal stem cell marker	Nestin
Both	Mesenchymal markers	Human leukocyte antigen A	HLA-A
		Human leukocyte antigen B	HLA-B
		Human leukocyte antigen C	HLA-C
		Endoglin	CD105
	Fibroblast markers	CD166/ALCAM	
		Cluster of differentiation 90	CD90
		CD44	
		Integrin beta-1	CD29
		ecto-5'-nucleotidase	CD73/NT5E
		CD9	
Fibroblast stromal cells	Fibroblast markers	Vimentin	VIM
		N-cadherin	CDH2
		Fibroblast specific protein-1	FSP-1/S100A4
		Melanoma cell adhesion molecule	CD146/MCAM

Fig. 5 Pluripotent lineages of amnion epithelial cells and amnion mesenchymal stem cells. (A) Amnion epithelial cells and (B) amnion mesenchymal stem cells can differentiate into cells that derive from the ectoderm, endoderm, mesoderm, and the outer cell mass. Each cell type graphically represented contains the *organ* or system name above and the name of the cell type below.

Summary

Membranes play a key role in the labor cascade by undergoing tissue- and cellular-specific changes that lead to the propagation of labor-initiating signals at term and preterm. As the fetal–maternal interface, if studied properly, the fetal membranes could answer many of the field's questions regarding term labor initiation, inflammation, infection, and diseases which lead to preterm birth. To better understand the mechanism behind the labor cascade, all aspects of fetal membrane origin, as well as cellular characteristics, need to be taken into account. Thus, providing a global understanding of the role of fetal membranes in parturition potentiates the usefulness of membranes during pregnancy, and in the prevention of adverse pregnancies.

Human fetal membranes (placental membranes, amniochorionic membranes) are the innermost lining of the intrauterine cavity. Membranes are fetal tissue in origin, start developing when fetal growth begins and becomes a fully formed structure by 15th week of pregnancy. Fetal membranes are constituted by amnion and chorion connected by collagen rich extracellular matrix forming the innermost layers of the intraamniotic cavity. Extracellular matrix made of fibrous proteins embedded in a polysaccharide gel and various collagen types provide the architectural and structural framework of the fetal membranes respectively. Amnion is constantly bathed in amniotic fluid, signifying its importance as a primary responder to changes in the amniotic cavity. Chorion is in close proximity to maternal decidua and maintains the immune tolerance at the maternal–fetal interface. Membranes perform multiple functions during pregnancy and act as the first line of defense to protect the fetus from mechanical and microbial insults. Membranes express over 400 functionally relevant biomarkers involved in membrane remodeling to maintain homeostasis during pregnancy. Hostile intrauterine environment can force homeostatic imbalance leading to its dysfunction that can contribute to adverse outcomes. Fetal membranes growth and functions are correlated very well with fetal growth; however, membranes are structurally and functionally independent from placenta. Recently, we have reported multiple evidence suggesting that fetal membranes undergo a telomere dependent aging process and membrane's longevity matches that of fetal growth and development. Histologic and molecular evidences suggest that intrauterine redox status helps the membrane to remodel during gestation whereas imbalance in redox status experienced at term accelerates fetal membrane senescence. Membrane senescence is mediated by stress responding kinase p38 mitogen activated kinase. Senescence associated fetal membrane inflammation increases overall uterine inflammatory load prompting parturition associated changes throughout uterine cavity. Thus, fetal membranes not only help to maintain pregnancy but also assist in delivery. Fetal membranes and cells of the fetal membranes are not dead tissues up on delivery. They are rich in pluripotent stem cells. Intact membranes or isolated membrane stem cells are used extensively for various medical applications. This book chapter highlights various functions of human fetal membranes that include, structure, function, biomarkers, mechanisms of membrane aging, its role in parturition and usefulness of fetal membranes and its stem cells postpartum.

Glossary

CYP 11B2 Aldosterone synthase.

CYP17 17 α -Hydroxylase/17,20-lyase (CYP17).

CYP21 21-Hydroxylase.

Dax-1 Dosage sensitive sex reversal adrenal hypoplasia congenital critical region on the X chromosome.

DHEA Dehydroepiandrosterone.

DHEAS DHEA sulfate.

DZ Definitive zone.

EGR1 Early growth response 1.

FZ Fetal zone.

HFA Human fetal adrenal.

HSD3B2 3 β -Hydroxysteroid dehydrogenase type 2.

NGFIB Nerve growth factor IB.

SULT2A1 DHEA sulfotransferase.

TZ Transition zone.

Introduction

Of all the endocrine glands in the human fetus, the adrenal has perhaps aroused the greatest interest. The human fetal adrenal (HFA) glands secrete very large quantities of steroid hormones; indeed it can be computed that the adrenals of some human fetuses near term secrete 100–200 mg steroids daily, most of which is in the form of dehydroepiandrosterone sulfate (DHEAS). The rate of steroid secretion by the fetal adrenals may be five times that of the adrenal of adults at rest (Siiteri and MacDonald, 1966; Easterling et al., 1966b). The human fetal adrenal has steroidogenic activities that may play a pivotal role in the normal development of the fetus and in the regulation of events leading to parturition.

During human pregnancy the rate of estrogen production increases strikingly. In fact, the production rate of estriol in near-term pregnant woman is 1000-fold greater than that in nonpregnant woman (Brown, 1956). The primary site of estrogen production is the placenta and it relies on the fetal adrenal gland to provide the essential C₁₉ steroid (DHEA/DHEAS) as substrates for placental estrogen (Pritchard and MacDonald, 1980). This was previously attributed to the fact that the human placenta lacks the steroid metabolizing enzyme 17 α -hydroxylase/17,20-lyase (CYP17) to convert progesterone or pregnenolone to DHEA. However, Escobar et al. (2011) have recently demonstrated the presence of CYP17 protein expression and activity in human trophoblasts in vitro, suggesting a larger contribution by the placenta in providing androgenic precursors than previously thought. The regulation of CYP17 in the placenta is still unclear. About 80% of maternal estriol is derived ultimately from fetal adrenal DHEA through the increased activity of placental aromatase. In addition, cortisol is also secreted by the adrenal gland during fetal life but, as will be discussed, at rates considerably less than that of DHEA.

Historical Background

The extremely large relative size of the human fetal adrenals has been recognized for almost 200 years (Lanman, 1953). The uniqueness of the HFA gland was first reported 100 years ago by four separate groups of investigators (Starkel and Wegrzynowski, 1910; Thomas, 1911; Kern, 1911; Elliott and Armour, 1911). They described the rapid growth of the HFA gland during fetal life and the existence of primarily two functionally and histologically distinct zones called the fetal zone (FZ) and the definitive zone (DZ) also known as the adult zone. Furthermore, this group of investigators demonstrated clearly the rapid involution of the former during the first few weeks after birth Fig. 1. The transient fetal zone is not present in most mammals and is unique to humans and a few nonhuman primates. This dramatic decrease in the HFA size after birth, up to 50% (Lanman, 1953), is largely attributed to atrophy of the FZ through apoptosis (Spencer et al., 1999).

Fig. 1 Size of the adrenal gland and its component parts during fetal life, during infancy, and during childhood. Adapted from Bethune, J. E., *The adrenal Cortex: A scope monograph*, Upjohn, 1974.

Embryology and Histology

The cells comprising the adrenal cortex arise from coelomic epithelium. The cells of the fetal zone can be identified as early as the seventh week of gestation (Keene, 1927; Uotila, 1940). Thereafter, the adrenals of the human fetus continue to grow, and the most rapid rate of growth is detected during the last 6 weeks of gestation (Spector, 1956). At 28 weeks of gestation, the size of the adrenal gland may be equal to the size of the kidney, and the ratio of the weight of the adrenal to total body weight at term is 15–20 times that of the adrenals of the adult (Carr and Simpson, 1981b).

As mentioned above, the HFA is comprised of three histologically distinct zones; the fetal zone, the transitional zone, and the definitive zone also known as the neocortex. The fetal zone accounts for the bulk (80%–90%) of the HFA. It is located centrally and contains large eosinophilic cells with pale staining nuclei. It is the primary site of growth and steroidogenesis. The definitive zone, or neocortex, surrounds the fetal zone and comprises a narrow band of tightly packed cells that has a small quantity of cytoplasm and dark staining nuclei. Fig. 2. It is thought to give rise to the postnatal adrenal glomerulosa. In the second trimester, the transition zone (TZ) develops between the fetal zone and the definitive zone. Cells in the TZ have the capability to synthesize cortisol and is thought to give rise to the postnatal zona fasciculata.

Fig. 2 Photomicrograph of histological section of the adrenal gland obtained from a 14-week-old abortus. The FZ accounts for the bulk (80%–90%) of the HFA and is the primary site of growth and steroidogenesis. The DZ surrounds the FZ and is thought to give rise to the adult adrenal glomerulosa. Original magnification, $\times 33$. FZ, fetal zone; DZ, definitive zone.

Function of the HFA

The primary function of the HFA is to provide steroids, i.e., DHEA and DHEAS, as precursors for the placenta to use in estrogen production. The zones of the HFA are functionally distinct in its steroidogenic roles (Suzuki et al., 2000; Mesiano et al., 1993; Mesiano and Jaffe, 1997). In addition to DHEAS, the fetal zone produces large amounts of other sulfated delta-5 steroids, including pregnenolone sulfate and 17 α -hydroxypregnenolone sulfate. The definitive zone expresses the enzymes needed for production of aldosterone but does not express 17 α -hydroxylase or DHEA—sulfotransferase (SULT2A1). During the second half of gestation the transitional zone expresses both 17 α -hydroxylase and 3 β -hydroxysteroid dehydrogenase type II (HSD3B2), allowing production of fetal cortisol. HSD3B2 is the enzyme needed for the conversion of delta-5 (pregnenolone) to delta-4 steroids (17 α -hydroxypregesterone). During most of gestation, the fetal adrenal lacks HSD3B2, preventing cortisol and aldosterone synthesis and directing steroid production toward DHEAS production. High expression of SULT2A1 in the fetal zone accounts for sulfonation of most of the delta-5 steroids produced, including DHEA and pregnenolone (Suzuki et al., 2000; Mesiano et al., 1993). Near birth, cells of the definitive zone, which express only HSD3B, acquire cytochrome p450 aldosterone synthase (CYP11B2) and begin to secrete mineralocorticoids such as aldosterone. These observations point to the regulation of steroidogenic enzymes being a critical determinant in modulating the biosynthetic capacity and the steroid products of the fetal adrenal gland.

It has been demonstrated that the levels of DHEA in cord plasma increase during pregnancy (Parker and Carr, 1981). After birth, plasma DHEA levels fall precipitously and remain low through childhood until adrenarche, when the levels again rise once more (Parker and Odell, 1980). In contrast, during fetal life cortisol is secreted in smaller quantities as determined on the basis of its concentration in cord plasma (Chang et al., 1976; Barnhart et al., 1980; Campbell and Murphy, 1977) and as determined in vitro studies of adrenal tissue during the first few days of culture (Huhtaniemi, 1977; Simpson et al., 1979; Carr et al., 1980; Branchaud et al., 1978). Although cortisol levels may increase slightly between early and late gestation (Pearson Murphy and Diez D'aux, 1972), there is little evidence to suggest changes in cord plasma cortisol concentration after 25 weeks until term, in contrast to DHEAS levels (Parker and Carr, 1981; Hauth et al., 1978). However, this cannot be construed to mean that the rate of cortisol secretion does not increase as a function of gestational age. As the fetus grows and matures, it is probably that fetal metabolic clearance of plasma cortisol increases. Indeed, the levels of cortisol and cortisol sulfate in amniotic fluid increases as pregnancy advances (Belisle and Tulchinsky, 1980). A significant amount of cortisol in plasma (25%–50%) is derived from maternal sources (Beitins et al., 1973). However, maternal cortisol is converted extensively to cortisone by the placenta during transfer to the fetus (Beitins et al., 1973; Murphy et al., 1974). It is believed that the low secretory rate of cortisol relative to that of DHEAS by the HFA is due to a relative deficiency or reduced activity of HSD3B2 in the fetal zone cells (Goldman et al., 1966; Cavallero and Magrini, 1967). It has been proposed that estrogens or other factors produced by the placenta are responsible for the inhibition of HSD3B2 (Voutilainen and Kahri, 1980).

Lipoproteins as a Source of Cholesterol for Fetal Adrenal Steroidogenesis

As has already been discussed, the adrenal glands of the near-term human fetus secrete large quantities of steroid hormones, 100–200 mg/day. This is a 5–10 times the rate of steroid secretion by the adrenal glands of adults at rest. An important question that arises is the origin of the precursor utilized by the fetal adrenals for steroid hormone biosynthesis.

Cholesterol serves as the principal precursor for steroid biosynthesis in the HFA. LDL binds to a population of receptors present in high concentrations on the cell membranes. Adrenocorticotrophic hormone (ACTH) causes an increase in the number of LDL binding sites, thus optimizing the uptake of LDL cholesterol for steroidogenesis. Fetal adrenals could obtain cholesterol for steroidogenesis from two sources: (1) de novo synthesis from C₂-units and (2) lipoproteins in the fetal plasma. The HFA is capable of de novo synthesis of delta 5-3 β -hydroxysteroid sulfate from C₁₄ acetate, however, based on the large capacity of the fetal adrenals for steroid biosynthesis, de novo synthesis can only account for 30% of daily steroid secretion (Parker and Schimmer, 1997). Thus the remainder of the cholesterol utilized by the HFA gland for steroid hormone biosynthesis is likely obtained from LDL in the fetal circulation. The placenta utilizes large quantities of maternal LDL-cholesterol that is taken up by the placenta and degraded. Because of the rapid rate of utilization of LDL by the HFA, fetal plasma levels of LDL are low and activity of the HFA is a primary determinant of these levels. Thus, in the case of anencephaly, in which the activity of the adrenal is very low, plasma levels of LDL are 2–3 times higher than in normal fetuses, whereas plasma HDL levels are unchanged (Carr and Simpson, 1981b). In addition, in the normal neonate plasma LDL levels rise rapidly after birth, and this event is coincident with the involution of the fetal zone of the adrenal. The fetal liver is likely to be the major source ultimately of the LDL-cholesterol utilized by the HFA. Consequently, factors that regulate cholesterol and lipoprotein synthesis in the fetal liver may, in turn, affect the steroidogenic activity of the HFA through regulation of the supply of cholesterol precursor. Thus, if trophic factors for the HFA other than ACTH exist, an important site of their action might be the fetal liver, rather than a direct action to influence the rate of synthesis of steroids by the fetal adrenal.

Gene Expression Differences in HFA

The HFA and adult adrenal gland have differences in structure and function that, until recently, was not well defined. It was hypothesized that gene expression likely played a critical role in defining their distinct steroidogenic and structural phenotypes. Recent

advances in molecular biotechnology, particularly with cDNA microarrays, has allowed for a more global understanding of gene expression in the HFA and adult adrenal gland.

Using cDNA microarrays, [Rainey et al. \(2001\)](#) contrasted human fetal (15–20 weeks) and adult adrenal gland gene expression profiles and discovered 69 transcripts that have greater than 2.5-fold differences in gene expression. Insulin-like growth factor—II (IGF-II) showed the most striking difference in expression with a 25-fold greater levels in the HFA than in the adult adrenal. In addition, the IGF-II transcript is one of the 20 transcripts consistently shown to have the highest signal intensities in the HFA. The enhanced HFA expression of IGF-II transcripts (second only to the liver) is well documented ([Han et al., 1988](#)). Not unexpectedly, the expression of 24-dehydrocholesterol reductase (DHCR24), an enzyme involved in cholesterol biosynthesis, was expressed at four times higher levels in the HFA than adult adrenal, again emphasizing the importance of de novo cholesterol biosynthesis in HFA steroid production.

Differences in gene expression profiles can result from numerous factors including alterations in key transcription factors that influence specific gene targets. [Rainey et al. \(2002\)](#) identified two transcription factor transcripts, early growth response-1 (EGR1) and nerve growth factor IB (NGFIB) that exhibited at least a 5-fold higher expression than seen in the HFA. EGR1 is a rapid response gene that controls the transcription of numerous response genes including phenylethanolamine *N*-methyltransferase gene in the adrenal medulla ([Ebert et al., 1994](#)). Its elevated expression in the adult adrenal over the HFA may be due to the presence of a fully developed medulla in the former. NGFIB is an important regulator of transcription of several steroidogenic enzymes including CYP21, HSD3B2 and CYP11B2 ([Bassett et al., 2004a,b](#); [Wilson et al., 1993](#); [Martin and Tremblay, 2005](#)). Both microarray and northern analysis have demonstrated a much higher expression of NGFIB in adult adrenal cortex under the control of ACTH ([Davis and Lau, 1994](#)). Multiple studies using transfection into adrenocortical cells have shown that NGFIB is a potent enhancer of HSD3B2 transcription ([Goto et al., 2006](#); [Bassett et al., 2004b](#)).

An extensive body of evidence in identifying steroidogenic factor 1 (SF-1) and dosage-sensitive sex reversal adrenal hypoplasia congenital critical region on the X chromosome (Dax-1), two nuclear transcription factors, as essential for the development and differentiation of the adrenal cortex ([Parker and Schimmer, 1997](#); [Morohashi, 1999](#); [Bakke et al., 2001](#); [Lalli and Sassone-Corsi, 2003](#); [Lyer and McCabe, 2004](#)). SF1 is detected in the HFA from its earliest stages of development and is expressed in all zones of the human adult adrenal cortex. SF-1 regulates the transcription of a diverse array of genes involved in steroidogenesis, reproduction, and sexual differentiation ([Parker and Schimmer, 1997](#); [Parker et al., 2002](#)). Human patients with SF-1 mutations have primary adrenal insufficiency and sex reversal ([Beuschlein et al., 2002](#); [Achermann et al., 1999](#); [Hammer et al., 2005](#)). Dax-1, another orphan nuclear receptor, is known to be responsible for human X-linked congenital adrenal hypoplasia, which is characterized by adrenal insufficiency in infancy and hypoplasia of the HFA with an absence of DZ. Much of its role in adrenal development was revealed through the study of Dax-1 mutations in humans. Dax-1 is also expressed in the HFA in its earliest stages of development and its pattern of expression overlaps significantly with SF-1, suggesting a coregulatory role in steroidogenesis and adrenal gland development ([Beuschlein et al., 2002](#)).

Considerable progress has been made in the last several decades in defining the genes that regulate steroidogenesis and adrenal cortical development, however, most aspects of this process remain poorly understood.

Regulation of HFA Growth

Numerous in vitro and in vivo studies have demonstrated that ACTH is the major trophic hormone that regulates the growth and stimulation of steroid secretion by the HFA. The adrenal glands of human anencephalic fetus lacks the striking increase in the size of the HFA achieved by fetus of normal gestation. The smaller size of the adrenal glands of the anencephalic fetus is thought to be due to atrophy or involution of the fetal zone which comprises 80% of the gland in normal fetuses near term [Fig. 3](#). Adrenal trophy is believed to be due to the low levels of ACTH in plasma of anencephalic fetuses ([Easterling et al., 1966a](#); [Allen et al., 1974](#)). Additionally, maternal glucocorticosteroid therapy leads to suppression of the fetal adrenal steroidogenesis presumably by suppression of fetal ACTH secretion ([Ballard et al., 1980](#)). ACTH is known to promote hypertrophy and production of DHEAS and cortisol by HFA in vitro ([Rainey et al., 2004](#)). Taken together these data indicate that ACTH is needed for fetal adrenal DHEA production. However, the massive amount of fetal steroidogenesis and hypertrophy of the gland as pregnancy progresses cannot be explained by ACTH alone as its level does not rise significantly during the last trimester of gestation ([Branchaud et al., 1978](#)). Therefore, it is hypothesized that other factors, such as placenta derived factors, are responsible for the growth and differentiation of HFA in the later half of pregnancy. This is further supported by the observation that the HFA undergoes rapid involution immediately after birth when placenta derived factors are no longer available.

There is now evidence that placental corticotropin releasing hormone (CRH) may play an integral role in regulating the increase in fetal adrenal steroidogenesis during the last weeks of gestation. CRH is a 41-amino acid peptide that was first identified in the hypothalamus but is also produced by the human placental, fetal membranes, and decidua. CRH controls the ACTH release by the anterior pituitary and thus cortisol and DHEAS secretion by the HFA. Unlike hypothalamic CRH, which is under the negative feedback control of glucocorticoids, cortisol stimulates placental CRH production ([Robinson et al., 1988](#); [Jones et al., 1989](#); [Karalis and Majzoub, 1995](#)). Increase in placental CRH drives HFA cortisol production and vice versa, creating a potent positive feed back endocrine loop between fetal adrenals and the placental that is only terminated when the placenta and fetus separates at the time of delivery.

Fig. 3 Photomicrograph of a histological section from the adrenal gland obtained from a 36-week-old anencephalic newborn. The smaller size of the adrenal glands of the anencephalic fetus is thought to be due to absence or involution of the FZ. FZ, fetalzone; DZ, definitive zone.

Maternal plasma CRH levels are decreased in the first trimester and increase from midgestation to term. In the last 12 weeks of gestation, CRH plasma levels increase considerably, peak during labor, and decrease precipitously after delivery (Goland et al., 1986; Stalla et al., 1989). Umbilical cord blood levels and amniotic fluid levels of CRH are increased similarly in late gestation (Lockwood et al., 1996). Fetal CRH levels are lower than those in maternal circulation (50 vs. $1000 \times 10^{-9} \text{ mol/m}^3$) but are substantial compared with levels in men and nonpregnant women. The ability of CRH to directly stimulate human fetal adrenal to produce cortisol and DHEA is well documented (Lanman, 1953; Spencer et al., 1999; Keene, 1927). Sirianni et al. (2005) have also demonstrated that CRH induces ACTH-R expression and cortisol production in HFA in vitro. In primates, CRH is the only trophic hormone to have a specific serum-binding protein (CRH-BP) that binds CRH in the fetal and maternal compartments to tightly regulate the bioactivity of placental CRH (Parker and Carr, 1981). CRH-BP levels decrease in later half of pregnancy, whereas CRH levels increase in maternal plasma and in amniotic fluid. Changes in CRH-BP levels may explain the increase in steroidogenesis in HFA despite relatively constant levels of circulating ACTH in the later half of pregnancy.

Placental CRH may be a key regulator of the fetal-placental stress response machinery as well as in initiation of parturition in humans. In pregnancies in which the fetus can be considered to be stressed as a result of various complications, such as intrauterine growth restriction or preeclampsia, the concentrations of CRH in fetal plasma, amniotic fluid, and in maternal plasma are increased over those seen in a normal gestation (Barnhart et al., 1980; Campbell and Murphy, 1977; Huhtaniemi, 1977). In women who delivered preterm, there was a more rapid rate of increase in CRH levels from the 2nd trimester. Moreover, the biologic impact of increased CRH levels is likely to be amplified in such instances as a result of subnormal levels of CRH-BP (Carr et al., 1980; Branchaud et al., 1978). Such increases in placental CRH production during normal gestation and the excessive secretion of placental CRH in complicated pregnancies may play a role in the normal gestational increases in fetal adrenal cortisol synthesis (Murphy et al., 1974) and the supranormal levels of cortisol in umbilical cord blood that occurs in stressed infants (Barnhart et al., 1980; Hauth et al., 1978; Belisle and Tulchinsky, 1980).

HFA and Parturition

The origin for the signals that control the onset of human labor involves complex biochemical dialog between the mother, fetus, and placenta and is a subject of debate even today. In humans, there are several potential contributions of the fetal adrenal to the timing of parturition. The initiation of fetal adrenal cortisol, which occurs late in gestation, may act in the feed-forward cascade that involves placental CRH as mentioned previously. Some investigators proposed that the increasing level of CRH at the end of gestation reflects a “fetal/placental clock” (i.e., that the human placenta and fetus, through endocrine events, determine the timing of parturition at the end of the normal gestational term) (Carr and Simpson, 1981a,b). The increasing levels of fetal adrenal production of DHEA-S (and its conversion to estrogen) stimulates the production of contraction-associated proteins within the myometrium, resulting in coordinated myometrial activity and onset of labor. This hypothesis is supported by the observation that women who have steroid sulfatase deficiency, which blocks placental use of sulfated precursors, have prolonged pregnancies (Rainey et al., 2001). CRH also stimulates fetal adrenal glands to produce large amount of cortisol, which has numerous effects on preparing fetal organ systems (by fetal lung maturation) and maternal organ systems (by promoting expression of placental genes such as oxytocin and prostaglandins) for labor.

Summary

The human fetal adrenal glands undergo profound physiologic changes during gestation that are unparalleled in any other human endocrine organ. Their steroid products are important for fetal organ maturation and for the correct timing of parturition. Together with the placenta and the maternal adrenal, they form a unique maternal/fetal endocrine unit/system. The development and function of the human fetal adrenal is distinct from those in other species. Their role in steroidogenesis and parturition remains incompletely understood despite more than a century of investigation. However, advances in biotechnology and study of patients with adrenal development disorders have helped to elucidate some of the factors involved in steroidogenic activity regulation and well as factors involved in HFA development and function. The human fetal adrenal is a fascinating organ unique to humans—its biophysiology, regulation, and development continues to remain a fertile area of research.

Fetal Hypothalamus–Pituitary

The fetal hypothalamus develops very early in gestation and is comprised of distinct functional nuclei that produce a diverse set of small proteins termed neuropeptides and the biogenic amine dopamine which coordinate multiple aspects of neural/neuroendocrine function. Under the coordinated expression of a growing number of ligands and transcription factors, including Sim 1, Brn-2, Otp, Gsh-1, sonic hedgehog, bone morphogenetic proteins and thyroid hormone, the hypothalamic nuclei that control pituitary-endocrine gland function are identifiable by the 6th week of gestation (Bakos et al., 2016; Morales-Delgado et al., 2014). As shown in Fig. 1, cell bodies of magnocellular neurons in the paraventricular (PVN) and supraoptic (SON) nuclei produce arginine vasopressin (AVP) also known as antidiuretic hormone (ADH) and oxytocin (OXT), respectively, which are axonally transported to and stored/released from the posterior pituitary. Cell bodies of parvocellular neurons in the PVN and anterior PVN (aPVN) produce thyrotropin releasing hormone (TRH), corticotropin releasing hormone (CRH), and growth hormone inhibitory hormone/somatostatin (SS) and those in the arcuate nucleus (ARN) produce growth hormone releasing hormone (GHRH), gonadotropin releasing hormone (GnRH) and the prolactin inhibitory hormone, dopamine. The axons of all cell bodies traverse the median eminence (ME) and neuropeptides are released into the pituitary portal vasculature and secreted into the anterior pituitary gland. In addition to production of these factors, other neurons in cell bodies of the PVN, SO, and ARN as well as those in the ventromedial nucleus (VMN) produce an array of neuropeptides, for example, urocortins, Substance P, enkephalins, Neuropeptide Y, and agouti-related peptide, that impact metabolic as well as reproductive function. Elegant studies in mice (Morales-Delgado et al., 2014) support the more current prosomeric model of hypothalamic development and have identified the rostrocaudal and dorsoventral regions of the hypothalamus in which the CRH, TRH, GHRH, and SS neurons originate, defined the spatiotemporal mRNA expression of these peptidergic factors during fetal development and confirmed that mRNA expression is initiated as early as embryonic day 9. In contrast to neural origin of all other hypothalamic peptidergic neurons, GnRH neurons originate from epithelial progenitor cells of the olfactory placode and GnRH mRNA in the ARN is expressed by gestation week 10. Hypothalamic expression of AVP and OXT is thought to occur relatively late in gestation and based on studies in sheep AVP/OXT neurons are functional and respond to physiologic challenge. While ADH decreases fluid production by and increases fluid reabsorption in the fetal lung following delivery, the specific role(s) of fetal OXT remain to be elucidated.

The program that orchestrates development of the hypothalamus is intricately linked to that guiding development of the pituitary gland which is composed of two anatomically and functionally distinct entities, the posterior pituitary and the anterior pituitary (Kaiser and Ho, 2016). The anterior pituitary which is fully developed by week 3 of gestation, is derived from Rathke's pouch, an ectodermal invagination anterior to the roof of the mouth. In addition, as Rathke's pouch proliferates toward the 3rd ventricle, cells fuse with the diverticulum and the latter along with neural ectoderm associated with development of the 3rd ventricle gives rise to the posterior pituitary. The anterior pituitary vasculature is evident by week 7 and a fully functional system is in place by

Fig. 1 Overview of the major hypothalamic nuclei producing neuropeptides. Paraventricular and supraoptic nuclei contain neurons producing corticotrophin-releasing hormone, urocortins, thyrotropin releasing hormone, oxytocin, and vasopressin. Ventromedial nucleus neurons produce Substance P, enkephalins, and Neuropeptide Y. Arcuate nucleus neurons express agouti-related peptide, Neuropeptide Y, proopiomelanocortin, melanocyte-stimulating hormones, adrenocorticotrophic hormone-stimulating hormone, and endorphins. Reproduced with permission from Bakos, J., Zatkova, M., Bacova, Z., Ostatnikova, D. (2016) The role of hypothalamic neuropeptides in neurogenesis and neuritogenesis. *Neural Plasticity*, 2016, 3276383, 10 pages.

midgestation. The major cell types of the anterior pituitary, which include corticotrophs, somatotrophs, gonadotrophs, lactotrophs, and thyrotrophs, are derived from totipotent stem cells in a highly coordinated and spatiotemporally controlled process which is completed by week 12 of gestation. The elucidation of the multiple factors that control pituitary cell lineage are based on studies in rodent/murine models and corroborated by pathologic/histologic observations in human subjects (Zhu et al., 2007). Early development requires expression of Rtx and Ptx and subsequent expression of LIM homeodomains by cells of Rathke's pouch as well as FGF8, BMP4 and sonic hedgehog and Pit1 by oral ectoderm and subsequently all pituitary cell types (Fig. 2).

Corticotropes are identifiable by week 6 and produce the peptide hormone ACTH which is a proteolytic product of proopiome-lanocortin (POMC). ACTH protein is detectable by week 7 of gestation and important for fetal adrenal cortical development and production of the steroid hormone dehydroepiandrosterone (DHEA) and its sulfate DHEAS, processes which are curtailed in fetuses with anencephaly/no pituitary. The melanocyte stimulating hormone (MSH) α MSH is a product of the posttranslational processing of precursor ACTH in humans and nonhuman primates and a product of melanotrophs that comprise the intermediate lobe of the anterior pituitary in other species for example, rodents. Fetal serum ACTH levels increase in late gestation in sheep and play a role in onset of parturition. Whether ACTH levels exhibit a similar pattern and function in the primate is equivocal and as discussed below likely reflects the complex interplay between maternal cortisol and impact of placental cortisol metabolism on the fetal-pituitary

adrenal axis as well as the impact of estrogen on zone specific regulation of fetal adrenal ACTH receptor expression and targeting to the cell membrane. Somatotrophs are evident by week 7 and produce the protein hormone growth hormone (GH), which is identifiable by week 8 and acts primarily by enhancing production of insulin like growth factor (IGF)-I. Fetal GH levels increase between weeks 15–25 of gestation and decline precipitously thereafter, presumably reflecting increased response of somatotropes to hypothalamic SS. Because fetuses with idiopathic GH deficiencies exhibit near normal growth, the role of fetal GH appears primarily on intermediary metabolism and thus levels are influenced by supply of maternal nutrients. Lactotroph expression of the protein hormone prolactin is initiated around week 16 of gestation and fetal serum levels steadily increase thereafter and are maximal at term. The increase in fetal prolactin is primarily regulated by fetal estradiol either directly and/or via suppression of hypothalamic dopamine expression which when elevated for example, by bromocriptine, reduces fetal prolactin levels. Prolactin is thought to be important for fetal water and electrolyte balance and thus amniotic fluid osmolality and in concert with cortisol and thyroxine induces maturation of the fetal lung in sheep. The gonadotrophs and thyrotrophs produce the heterodimeric glycoprotein hormones LH, FSH, and TSH, respectively, which have a common α -subunit and a specific β subunit which are detectable by week 12 of gestation. LH and FSH levels increase by midgestation and exhibit sexual dimorphism with levels higher in females than in males due to feedback inhibition of gonadotrophs by elevated fetal testicular secretion of testosterone. However, in both males and females, fetal LH and FSH levels subsequently decline after midgestation due to negative feedback of increasing levels of estradiol on the fetal hypothalamus–pituitary (Dattani and Gevers, 2016). Thus, as discussed below, maturation of the fetal ovary and testes during the second half of gestation appears to be gonadotropin independent. Serum TSH levels are detectable by week 10, increase late in gestation and at term and it appears that TSH functions to regulate the fetal thyroid gland.

Fetal Endocrine Glands

Cellular Development and Secretions of the Adrenal Cortex and Medulla

The primate fetal adrenal is comprised of chromaffin cells and three distinct zones of cortical cells, which arise from intermediate mesoderm known as the adrenogonadal primordium (AGP) which also gives rise to the gonads. AGP development requires expression of Wilms tumor suppressor gene 1 (WT1) and its target SF1 and deletion of either gene results in agenesis of both the gonads and adrenal gland (Del Valle et al., 2017). Stem/progenitor cells also populate the subcapsular region of the fetal adrenal and during the course of gestation these cells migrate centripetally and thereby underpin the unique zone-specific and spatio-temporal pattern of fetal adrenal cortical growth that occurs in primates (Ishimoto and Jaffe, 2011). The primordial adrenal is evident by week 4 and upon activation of stem/progenitor cells, cortical cells undergo rapid growth resulting in a very large fetal zone (FZ) and two smaller zones, the definitive zone (DZ) in the outermost regions of which the progenitor cells reside and the transitional zone (TZ). The FZ synthesizes the androgens DHEA and DHEAS the levels of which steadily increase throughout human pregnancy and are essential for placental estrogen production (Albrecht and Pepe, 2014). Expression of enzymes catalyzing DHEA/S synthesis is evident at 9–12 weeks gestation and earlier in nonhuman primates. Based on these findings and that fetal adrenal growth is compromised in anencephalic fetuses, it appears that the pituitary–adrenal axis is operative very early in gestation. In contrast, cells of the DZ and TZ do not grow or produce aldosterone or cortisol, respectively, until late in gestation and yet these cells like the FZ express ACTH receptor and are ACTH dependent. Therefore, as discussed below additional factors play a significant role in coordinating fetal pituitary–adrenal axis function as well as control FZ growth (Albrecht and Pepe, 2014). The latter are of physiologic relevance as the timely ontogenesis of fetal adrenal cortisol production is important for maturation of fetal organ systems, for example, lung, and in sheep for onset of parturition. It remains to be determined whether aldosterone synthesis is sufficient to impact fetal homeostasis.

The chromaffin cells of the fetal adrenal are derived from the sympathetic nervous system. Neural cells migrate into the adrenal cortex early in gestation and ultimately coalesce to form the medulla, which exhibits the enzymatic capacity to produce the catecholamines epinephrine and norepinephrine as well as dopamine by midgestation. Production of medullary catecholamines is thought to be essential for coordination of fetal cardiovascular, respiratory and metabolic functions critical for intrauterine survival for example, response to stressors including hypoxia and transition to an extrauterine environment. Interestingly, the marked increase in serum epinephrine levels at birth is reduced in neonates with fetal adrenal 21-hydroxylase deficiency and thus lower TZ production of cortisol indicating that intraadrenal cortisol, is required for maturation of the fetal adrenal medulla.

Cellular Development and Secretions of the Thyroid

The thyroid originates from two lateral anlagen in the brachial pouches and from the median anlage which is an outpouching of the floor of the pharynx and the tip of the foramen caecum at the base of the tongue. As the median anlage descends through the neck, it fuses with the lateral anlagen and gives rise to follicular cells which acquire capacity to accumulate iodine obtained by placental transport of maternal stores and form the thyroid hormones thyroxine (T_4) and triiodothyronine (T_3) by week 11. The lateral anlage differentiates into the parafollicular “C” cells that synthesize the hormone calcitonin important for calcium homeostasis. The spatio-temporal expression of the genes/transcription factors controlling human fetal thyroid development have been identified (Polak, 2014; Dattani and Gevers, 2016). It is well established that small amounts of maternal thyroid hormones cross the placenta to control development of the fetus. The pattern of the fetal serum levels of the prohormone T_4 , the active hormone T_3 , the inactive hormone reverse T_3 (rT_3) and TSH in the human fetus are shown in Fig. 3. Although pituitary TSH is not essential for growth there

Fig. 3 Representation of the normal serum levels of total T_3 (triiodotyrosine), total T_4 (thyroxine), TSH (thyroid stimulating hormone), and reverse T_3 (rT_3) in the human fetus during weeks 20–40 of gestation (GW), at birth and at 24–120 h of postnatal life. Reproduced with permission from Polak, M. (2014). Human fetal thyroid function. *Endocrine Development* **26**, 17–25.

appears to be increased sensitivity of the fetal thyroid to TSH with advancing gestation since the levels of T_4 , the majority of which is bound to thyroxine-binding globulin synthesized by the fetal liver, continue to rise despite a slight decrease in TSH secretion. The tissue specific development of the deiodinase enzymes types I and II that convert T_4 to T_3 also play an important role in the responsivity of tissue to thyroid hormones. The placenta expresses high levels of deiodinase type III which converts T_4 to rT_3 and explains why fetal levels of rT_3 exceed those of T_3 . Although fetal tissues express receptors for T_3 , human infants born without a thyroid show no signs of hypothyroidism at birth and thus the transport of maternal hormone appears sufficient. However, athyroid infants will develop neural deficits/cretinism if not treated with T_4 . Thus, while the role of the fetal thyroid in human fetal development remains unclear, it is well established that the marked increase in TSH at birth that leads to a rapid and sustained increase in T_4 and T_3 in the perinatal period (Fig. 3) is critical for maturation of the CNS in the first few weeks of extrauterine life.

Cellular Development and Secretions of the Gonads

The gonads are comprised of germ cells which are derived from the yolk sac wall and somatic cells of the genital ridge that forms from the primitive mesonephros. (Del Valle et al., 2017). By week six, the primitive gonad is comprised of gonadal cords continuous with the surface epithelium and a dense internal cellular mass termed the gonadal blastema. At this point the gonad is structurally identical in both genetic male (XY) and female (XX) fetuses and termed the indifferent gonad, which is flanked by the primordia of the Wolffian and Müllerian ducts and the primordia of the external genitalia. Formation of the testis begins at week 7 and results from expression of the SRY gene on the Y chromosome and the genes SOX9, GATA4, and DAX1 (Fig. 4; Dattani and Gevers, 2016). Primitive cords lose their connection with the surface epithelium and Sertoli cells as well as spermatogonia begin to develop, while undifferentiated interstitium form Leydig cells which exhibit the enzymatic capacity to produce testosterone as early as week 8. Upon secretion of placental chorionic gonadotrophin (hCG) into the fetal circulation, the fetal Leydig cells initiate synthesis of testosterone which enhances transformation of the Wolffian duct into epididymis and vas deferens, while the Sertoli cells produce the glycoprotein hormone antimüllerian hormone (AMH) that causes involution of the Müllerian duct (Dattani and Gevers, 2016). Secretion of fetal testicular testosterone into the blood peaks at week 16–18 and declines thereafter in parallel with the decline in placental hCG synthesis (Albrecht and Pepe, 2014). Uptake by and conversion of testosterone to 5α dihydrotestosterone by primordia of the external genitalia leads to formation of prostate, phallus, and penile urethra. Although testicular growth and development continue throughout the second half of gestation, maturation appears to be coordinated by placental estrogen and not fetal pituitary gonadotrophin as discussed below.

In the absence of SRY and presence of a second X chromosome, the indifferent gonad will initiate formation of an ovary. The gonadal blastema differentiates into interstitium and medullary cords containing germ cells now termed oogonia. The genes that initiate ovarian formation remain to be elucidated although there is evidence for a role of Wnt4, DAX1, and SF1. The cells of the developing fetal ovary do not synthesize androgens or estrogens and are not responsive to hCG in vivo or in vitro. Thus, in the absence of any or little testosterone or AMH, the Wolffian duct involutes and the Müllerian duct differentiates into a uterus and oviduct and the primordia of external genitalia develop female. However, like the fetal testis, development of the fetal ovary even very early in gestation appears to be gonadotrophin independent and regulated by placental estrogen as discussed below (Pepe et al., 2006).

Fig. 4 Summary of the molecular and cellular events of gonadal differentiation. Reproduced with permission from Dattani, M.T. and Gevers, E.F. (2016). Endocrinology of fetal development. In: Melmed, S., Polonsky, K.S., Larsen, P.R. Kronenberg, H.M. (eds.) *Williams Textbook of Endocrinology* (13th edn.), pp. 849–892. Philadelphia, PA: Elsevier.

Cellular Development and Secretions of the Parathyroid

The 4 parathyroid glands originate from the 3rd and 4th pharyngeal pouches and development occurs in synchrony with that of the thyroid and appears to require expression of *HOX15* and several other genes also linked to thyroid formation (Kovacs, 2014). By week 6, the parathyroids become localized to the upper and lower poles of the thyroid and by week 10 are capable of producing parathyroid hormone (PTH). However, throughout most of gestation, fetal serum PTH levels are very low and serum calcium levels are markedly elevated which suppresses PTH production (Kovacs, 2014). Fetal hypercalcemia results from transport of large amounts (up to 150–300 mg/kg/day) of calcium to the fetus, which along with maternal derived phosphorous and magnesium is essential for fetal bone/tissue development and mineral homeostasis. Although fetal serum levels of PTH related peptides (PTHrp) primarily of placental origin are elevated throughout gestation, these peptides do not appear to play a major role in the fetus. Moreover, fetal serum levels of 1, 25 dihydroxyvitamin D₃ (calcitriol) that controls calcium uptake by the GI tract are also very low due to the low levels of PTH and consequently low levels of the renal 1 α -hydroxylase enzyme controlling conversion of precursor 25-hydroxyvitamin D₃ of placental origin to calcitriol. Thus, in the fetus the major hormone controlling fetal bone formation/mineralization is calcitonin produced by the parafollicular “C” cells of the thyroid in response to elevated levels of calcium and consequently fetal serum levels of calcitonin are increased throughout development.

Cellular Development and Secretions of the Endocrine Pancreas

The pancreas is derived from protrusions of the primitive gut epithelium (Edlund, 2002; Dattani and Gevers, 2016). The exocrine pancreas essential for production of enzymes and bicarbonate for digestion is developed by week 4 and the endocrine pancreas containing islets comprised of α and β cells that produce glucagon and insulin, respectively, as well as cells that synthesize somatostatin and pancreatic polypeptide, are identifiable by week 8. The development of α cells appears to peak at midgestation,

whereas β cells continue to proliferate throughout the second half of gestation. The genes controlling pancreatic formation include *IDX1*, *ISL1*, *PAX4*, and *PAX6* which when deleted leads to pancreatic agenesis, islet cell agenesis, and β or α cell agenesis/hypogenesis, respectively. The fetal pancreatic levels of insulin and glucagon are relatively high and increase between mid and late gestation. However, the infusion of glucose or arginine does not stimulate fetal insulin release and thus the capacity of the fetal β cell to release insulin and fetal serum levels of insulin are relatively low throughout most of gestation. In contrast, fetal glucagon levels are relatively high since α cell glucagon release is not responsive to glucose, that is, not suppressed by hyperglycemia. Thus, while fetal pancreatic α and β cells develop and synthesize glucagon and insulin, respectively throughout development, they are not responsive to feedback by glucose. Thus, it is generally thought that in the fetus insulin and glucagon may play a less important role in the regulation of the metabolism of substrate/glucose which is obtained by placental transfer of maternal stores by facilitated diffusion. The constant supply of maternal glucose also precludes a need for gluconeogenesis by fetal tissues and glucagon receptor expression in fetal liver is relatively low. Apparently, a complex interplay of factors for example, IGFs, adipokines produced by the fetus and placenta control the metabolic processes important for fetal growth (Albrecht and Pepe, 2014). However, by late gestation fetal insulin markedly increases glucose uptake and lipogenesis. The latter plus the onset of development of gluconeogenesis and need for glucagon to maintain blood glucose levels immediately after birth and the responsiveness of pancreatic α and β cells to glucose are rapidly established in late gestation/postnatally. It is important to note however, that in pregnancies complicated by maternal gestational diabetes and thus chronic fetal hyperglycemia, fetuses have elevated levels of insulin and exhibit β cell hyperplasia.

Hepatic and Adipose Endocrine Function

It is well established that IGF I and IGF binding protein (IGFBP)-3 produced by the fetal liver and IGF-I expressed in and acting in a paracrine manner in fetal tissues, for example, brain and bone, play a significant role in fetal growth (Dattani and Gevers, 2016). Thus, fetal growth is impaired in mice with mutations in or deletions of IGF-I or its receptor and fetal blood IGF-I levels are correlated with neonatal birth weight/size. Fetal IGF-I levels are modulated by nutrient availability and thus are reduced in nutritionally deprived animals. Administration of IGF-I to normal or growth restricted fetal sheep and guinea pigs increased or restored growth, apparently by upregulating placental nutrient transporters via activation of mammalian target of rapamycin (mTOR) (Albrecht and Pepe, 2014). In addition to the IGF system, the hormones adiponectin and leptin and proinflammatory adipokines for example, resistin, produced by adipose tissue also play a role in fetal growth (Martos-Moreno et al., 2009). Thus, compared to normal full term fetuses, umbilical cord levels of resistin are higher and levels of leptin, adiponectin, IGF-I and IGFBP-3 lower in infants born premature and small for gestational age. Thus, the increase in fetal serum levels of leptin and adiponectin with advancing pregnancy appears to reflect the increase in acquisition of adipose tissue by the fetus. However, our understanding of the factors regulating adipose tissue accumulation and adipokine production remains incomplete.

Role of Placental Estrogen on Fetal Organ System Development

Modulation of Placental Metabolism of Maternal Cortisol and Integration of the Fetal Hypothalamic–Pituitary–Adrenocortical Axis

As indicated earlier, the primate fetal hypothalamus and pituitary can synthesize CRH and ACTH, respectively, very early in gestation, whereas the transitional zone cells of the fetal adrenal cortex do not develop the capacity to produce cortisol until much later. Thus, the fetal pituitary–adrenal axis seems “out of phase” and only becomes functionally integrated near term. Studies have now shown that estrogen, by regulating the expression and cellular localization of the placental 11β -hydroxysteroid dehydrogenase (11β -HSD)-1 and -2 enzymes controlling the interconversion of cortisol–cortisone, dictates the level of biologically active maternal cortisol that arrives in the fetal circulation and via this mechanism plays a critical role in the timely activation of fetal pituitary ACTH dependent maturation of fetal adrenal cortisol synthesis (Albrecht and Pepe, 1999). As shown in Fig. 5, in the presence of relatively low levels of estrogen in early to midgestation, placental 11β -HSD-controlled metabolism favors the formation of cortisol, which is secreted into the fetal circulation and suppresses fetal pituitary ACTH production, thereby preventing ACTH dependent fetal adrenal cortisol production. With advancing gestation and increased estrogen production, there is increased placental 11β -HSD regulated conversion of maternal cortisol to cortisone which would decrease the amount of maternal cortisol arriving in the fetus. The latter results in disinhibition of and thus production of fetal pituitary ACTH and onset of cortisol synthesis by the fetal adrenal gland. In support of this hypothesis, the expression of fetal pituitary ACTH and its precursor pro-opiomelanocortin mRNA and expression of key steroidogenic enzymes in and the ontogenesis of de novo cortisol production by the baboon fetal adrenal were greater at term than at midgestation and increased prematurely at midgestation by treatment with estrogen which induced placental oxidation of cortisol to cortisone. Placental 11β -HSD-dependent regulation of the fetal pituitary–adrenal axis is also likely operative during human pregnancy as women with hypoadrenalism can maintain pregnancy without exogenous corticosteroid treatment, ostensibly because of premature activation of the fetal pituitary–adrenal axis in the absence of placental transport of maternal cortisol to the fetus.

Fig. 5 The role of estrogen (E_2) on placental 11β -HSD-catalyzed metabolism of cortisol (F) and cortisone (E) and regulation of the fetal pituitary-adrenocortical axis at mid- and late gestation in the baboon. 3β -HSD, Δ^3 - 3β -hydroxysteroid dehydrogenase. From Albrecht, E.D. and Pepe, G.J. (1999). Central integrative role of oestrogen in modulating the communication between the placenta and fetus that results in primate fetal-placental development *Placenta* **20**, 129–139.

Development of the Pool of Healthy Ovarian Oocytes/Follicles and Testicular Maturation Essential for Adult Reproductive Function

In primates, the formation of the pool of ovarian primordial follicles available for reproductive function in adulthood occurs in utero. Thus, following differentiation of the indifferent gonad into an ovary there is marked mitotic proliferation of somatic (pregranulosa) and germ (oogonia) cells early in gestation. As germ cells initiate meiosis but arrest in prophase 1 and are now termed oocytes, they make contact with the pregranulosa cells and form a germ cell nest in which primordial follicles are subsequently formed and released into the ovarian cortex by breakdown of the germ cell nest. The oocytes of these newly formed primordial follicles then develop microvilli which contact the single layer of surrounding granulosa cells from which they obtain nutrients to support their survival for up to 50 years (Pepe et al., 2006). Studies have shown that the human and baboon fetal ovary express $ER\alpha$ and $ER\beta$ and that fetal ovarian development is critically dependent upon the increase in estrogen production that occurs with advancing gestation. Thus, in fetal baboons deprived of estrogen in the second half of gestation, primordial follicle numbers were decreased by 50%, whereas germ cell nest breakdown was curtailed and thus the number of germ cell nests increased. Moreover, several of the primordial follicles that did form in ovaries of estrogen-deprived fetuses appeared unhealthy and contained oocytes with a marked depletion in microvilli. Additional studies showed that the onset of puberty was delayed and that serum estradiol and gonadotrophin levels in subsequent menstrual cycles altered in offspring of estrogen-deprived animals, indicating that estrogen programs mechanisms in fetal ovarian development critical for adult reproductive function (Pepe et al., 2006). The importance of estrogen in programming primate fetal ovarian development is heightened by studies showing that polymorphisms of the $ER\alpha$ gene in women are associated with premature ovarian failure and that reproductive function was disrupted in women born very premature and thus not exposed to the increasing levels of estrogen of advancing pregnancy.

Estrogen receptors are also expressed in the primate fetal testis and estrogen also appears to be essential for development of the pool of spermatogonial germ cells and Sertoli cells. Thus, in male fetuses deprived of estrogen during the second half of gestation, the number of reserve spermatogonia stem cells and the development of undifferentiated type A spermatogonia was reduced and the morphology of the seminiferous tubules disrupted. It is likely but remains to be shown whether these perturbations in the germ cell population and the integrity of the seminiferous cords in the estrogen-deprived animals impair spermatogenesis and fertility in adulthood. However, male mice with targeted disruption of the P450 aromatase gene that converts androgens to estrogen exhibit a decline in sperm number in association with infertility and ER α knock-out mice exhibit altered morphology of the testis, efferent ductules, and epididymis as well as reduced sperm motility and infertility (Albrecht and Pepe, 2014).

Control of Fetal Adrenal Fetal Cortical Zone Growth and Androgen Production

In addition to regulating the timely expression of fetal pituitary ACTH via control of placental cortisol metabolism, estrogen via interaction with ER α/β in the fetal adrenal DZ elicits direct effects on the fetal adrenal important for zone-specific development and function of the FZ. Thus, in fetal baboons deprived of estrogen in the second half of gestation, expression of the cell cycle regulator cyclin D1 was increased in the DZ in which progenitor cells essential for fetal adrenal DZ growth reside and the mass/volume of and production of DHAS by the FZ at term were markedly increased, whereas the volumes and steroidogenic function of the DZ and TZ were unaltered (Babischkin et al., 2016). Further study showed that estrogen acts by controlling the interaction of the ACTH receptor (termed the melanocortin 2 receptor; MC2R) with its MC2R accessory protein (MRAP) in the DZ critical for ACTH to elicit its effects. Thus, as shown in Fig. 6, in the first half of pregnancy, the relatively low levels of fetal estrogen promote interaction of MC2R with MRAP leading to movement of MC2R to the cell surface in the DZ, which permits binding of ACTH to MC2R and activation of the MC2R signal transduction pathway. The latter causes increased expression of cyclin D1, progenitor cell proliferation and migration to the FZ and thus increased growth and DHAS production for placental estrogen (E_2) formation. The progressive increase in estrogen levels with advancing gestation restrains MC2R/MRAP interaction and ACTH binding to MC2R, thereby controlling the extent of progenitor cell proliferation/migration and FZ growth and DHAS production to maintain levels of estrogen within a physiologic range.

In summary, the fetal endocrine glands develop very early in gestation and exhibit the potential to produce their respective neuropeptide, protein and steroid hormones by as early as week 6–12 of gestation. Fetal hormone production is critical to the maintenance of fetal homeostasis and growth and integrated with and coordinated in part by maternal and placental hormoneogenesis and placental transport of maternal nutrients. Hormones produced by the fetal endocrine glands are also important for the maturation of fetal organ systems important for neonatal survival in the perinatal period and development and function in adulthood.

Fig. 6 Proposed role of estrogen (E_2) in regulating the interaction of ACTH receptor (Melanocortin 2 Receptor; MC2R) with the Melanocortin Receptor Accessory Protein (MRAP) in the definitive zone (DZ) important for ACTH dependent growth and production of dehydroepiandrosterone sulfate (DHAS) by the fetal zone (FZ) of the primate fetal adrenal gland important for placental estrogen (E_2) production. Stages of Lung Development

The development of the respiratory tract begins early in gestation (as early as 3 weeks after conception, or 3 weeks of gestation) and extends until long after birth, with general agreement that development of new alveoli continues until at least 2 years of age, but with much contention that it can extend even longer into childhood and adolescence (Burri, 2006; Fraga and Guttentag, 2012). In this discussion, we will outline the development of the respiratory tract in chronologic order, noting the gestational age of the fetus at each crucial stage. For the purposes of this discussion, the upper respiratory tract will be defined as the airway extending from the nose and mouth to the vocal cords. Alternatively, the lower respiratory tract will be defined as the airway extending below the vocal cords to the alveolar-capillary interface in the lungs. "Alveolar" refers to the alveoli, or the numerous tiny air sacs where gas exchange occurs. It is important to note, however, that the upper and lower respiratory tracts, while they serve distinct functions and have distinct origins and compositions, exist as a *continuum*. During fetal and early postnatal life, the development of the respiratory tract is divided into five stages: embryonic, pseudoglandular, canalicular, saccular, and alveolar. However, these are not entirely distinct phases and exhibit a fair amount of overlap and variation.

Embryonic Stage (3–7 Weeks of Gestation)

The first sign of the burgeoning respiratory tract is the appearance of a groove and the budding of a saccular structure from the ventral (anterior) wall of the innermost layer of cells in the developing foregut (foregut endoderm) (Fig. 1). This primitive lung bud grows anteriorly and downward (ventrocaudally) in parallel with the developing foregut which will eventually become the upper gastrointestinal tract (esophagus). Both the lung and the esophagus are "foregut" structures (Kimura and Deutsch, 2007). The development of the lung bud and its growth in parallel with the future esophagus is coordinated by a complex milieu of transcription factors, i.e., factors that regulate the expression of specific genes and signaling pathways (Shojaie and Post, 2017; Fraga and Guttentag, 2012).

Fig. 1 Regulation of early lung development. Taken from Fig. 64–1 Transcription and growth factors known to regulate lung development from fetal and neonatal physiology, 5th edn. Polin, R., Abman, S., Rowitch, D., Benitz, W., 2017.

As we know, the mature respiratory system consists of two sides: a right lung, comprised of three lobes, and a left lung, comprised of two lobes, which are connected to the trachea and eventually the upper respiratory tract by right and left primary bronchi. This final lung structure is achieved via sequential, transcription factor- and growth factor-mediated branching of the primitive lung bud, along with complex interactions with the surrounding mesenchyme (mesodermal tissue that later develops into connective, lymphatic, circulatory, and skeletal tissues) to promote growth of distal epithelial cells only (Fraga and Guttentag, 2012; Warburton, 2017). This process is initiated at approximately 4 weeks of gestation when the developing lung bud is directed to divide into a right and a left branch, ultimately leading to the development of the right and left bronchi. Subsequent secondary branching results in the formation of three bronchial buds on the right and two bronchial buds on the left. During this stage, the early trachea and bronchial buds are lined by an epithelium of undifferentiated, closely packed cells in a layered array. This epithelium will eventually differentiate into cell types with varying functions including ciliated cells responsible for mucus clearance, secretory cells, basal cells responsible for the repair of injured epithelium, and submucosal glands aiding with immune function, among others (Fraga and Guttentag, 2012). These lung buds also initially lack cartilaginous support but cartilage formation begins at around 4 weeks gestation and proceeds caudally to be complete in the first few postnatal months. By 6–7 weeks gestation, smooth muscle expansion and neural innervation have begun, allowing fetal airway contraction.

During the embryonic stage of development, segmentation of the airway buds is accompanied by the development of the pulmonary (lung) blood vessels, or, vasculature. The mesenchyme surrounding the bronchial buds differentiates into an early vascular bed (vasculogenesis) which eventually connects both with the pulmonary arteries (originating from the 6th pair of aortic arches) and with the pulmonary veins (originating from the left atrium). During fetal life, the majority (90%) of blood flow is directed away from the pulmonary vasculature by the ductus arteriosus, connecting the pulmonary artery with the aorta, completely bypassing the lungs since the developing fetus does not rely on the lungs in utero for gas exchange; this function is provided by the placenta during fetal life (Fig. 2).

Pseudoglandular Stage (5–17 Weeks of Gestation)

The pseudoglandular stage of lung development is characterized by a gland-like appearance where further branching morphogenesis occurs, with the end result of formation of the primitive bronchial tree. Through the complex interactions between growth factors and mesenchyme initiated in the embryonic stage, the respiratory tubules continue to branch into more distal (terminal, or farther away from the center) bronchioles. By the 17th week of gestation, the distal airways consist of acinar tubules and buds (formations that resemble grape clusters) surrounded by mesenchyme (Wert, 2017). These distal airway formations will eventually become the mature adult pulmonary acini (singular: acinus) which represent the most distal ends of the airway, where gas exchange will occur at the alveolar-capillary interface (Fig. 3). While the actual size of the airways will increase throughout gestation and postnatal growth, branching of the large airways is completed in the pseudoglandular stage of fetal

development and no additional branching occurs. The expansion of cartilaginous support, smooth muscle, and neural innervation that began during the embryonic stage continues during the pseudoglandular stage. As the pulmonary vasculature continues to develop alongside the branching airways, the lymphatic system also originates, potentially budding from cardinal veins (Wert, 2017). The lymphatic vessels are very similar to blood vessels but transport lymph, composed of body fluid and white blood cells, instead of blood. The lymphatic vessels are critical later to clearing the lung fluid from the alveolar air spaces at the time of birth. Finally, the separation of the thoracic and the abdominal cavities occurs during the pseudoglandular stage and is a crucial step in development. This process of separation results from partitioning of the two compartments by the pleuroperitoneal fold. As the fetus grows, this fold is pushed down and back and eventually becomes immobilized at the midthoracic region anteriorly (toward the front) and at the lower thoracic region posteriorly (toward the back). Cells destined to become diaphragmatic muscle cells (myoblasts) and cells destined to form the phrenic nerves that stimulate the diaphragm (the large muscle that is used for breathing by lung expansion) migrate to the pleuroperitoneal fold to create the developing diaphragm and begin the process of neural innervation.

Canalicular Stage (16–26 Weeks of Gestation)

With the completion of the large airway branching in the pseudoglandular stage, the canalicular stage is characterized by the development of the rudimentary alveolar-capillary interface or gas exchange unit. A crucial element of the alveolar-capillary exchange is proximity of the air-containing alveolus with the blood-containing capillary, permitting easy diffusion of oxygen and carbon dioxide back and forth (Fig. 3). As a result, during the canalicular stage, development focuses on this ultimate goal of efficient gas exchange through expansion of the capillary bed and thinning of the intervening mesenchymal layer. Simultaneously, the rudimentary pulmonary acini are expanding exponentially yielding a surface area for gas exchange. As mentioned above, the acinus (plural: acini) derives from Latin and refers to formations that resemble grape clusters, with respiratory bronchioles as the stems and alveoli as the grapes (Fig. 3) (Wert, 2017). The canalicular stage is also characterized by significant changes in cellular differentiation of cuboidal epithelial cells into alveolar type I and type II epithelial cells in the alveoli. Differentiation of alveolar type II cells into flattened alveolar epithelial type I cells along the alveolar-capillary membrane results in the thin gas-permeable wall of the alveoli. The cube-like alveolar type II cells begin to have large stores of glycogen which will be used in the production of surfactant, a lipid and protein-rich substance that reduces surface tension so the air sacs stay expanded. As surfactant is produced by alveolar type II cells, it is packaged in multilayered lamellar bodies, ready to be secreted and coat the walls of the alveoli upon the first breath (Fraga and Guttentag, 2012). If this developmental stage progresses normally and without disruption, by its conclusion the fetus has epithelial cells capable of producing fetal lung fluid and the alveolar-capillary exchange system has been developed enough to function; however, actual surfactant production and total surface area for gas exchange in the fetus at this stage are still often not adequate to be compatible with appropriate lung function if preterm birth occurs.

Saccular Stage (24–38 Weeks of Gestation)

The saccular stage of fetal lung development is essentially a refinement in utilization of the basic structures developed during the previous stages. During this time of fetal lung development, there is further expansion of the acini with even further thinning of the mesenchyme, and therefore a further reduction in the distance required for diffusion of oxygen and carbon dioxide; the mean thickness of alveolar-capillary membrane at birth is $0.6\ \mu\text{m}$ (one millionth of a meter) (Wert, 2017). Overall surface area for gas exchange is increased through extension of the terminal saccules and alveolar ducts. There is also continued differentiation of cell types with the alveolar epithelial type II cells become increasingly efficient at surfactant production (including

producing surfactant-associated proteins A, B, C, D) and with the alveolar epithelial type I cells continuing to flatten and multiply to cover additional surface area and come into closer contact with the capillary vascular bed. In the mature lung, although the type I and type II cells are nearly equal in number, the much larger type I cells will cover >90% of the alveolar surface (Wert, 2017).

Alveolar Stage (36 Weeks of Gestation and Thereafter)

The final stage of lung development starts at around the time of delivery of term infants and continues well into childhood. At birth, lungs will have approximately 150 million alveoli, with an astonishing 4m² surface area available for gas exchange (approximately the size of a ping pong table!) (Ochs et al., 2004). During this time, the alveoli mature, creating even more surface area for gas exchange at the alveolar-capillary membrane. To further increase the gas exchange surface there is also development of secondary alveolar septa (or secondary crests) which begin as ridges forming from the primary septa and which are thinner and longer than the more primitive primary septa. This creation of ridges or secondary crests from the primary septa appears to be influenced at least partly by crosslinking of elastin and collagen already deposited in the primary septal structure (Delacourt and Hadchouel, 2017). Additionally, while a double capillary network was initially developed surrounding each primitive alveolar septa, this network is reorganized into a single capillary bed associated with each mature alveolus. There is massive cellular proliferation during this stage, with an increase in both alveolar type I and type II epithelial cells, as well as endothelial cells.

Fetal Lung Expansion and Fetal Lung Fluid

Achievement of the complex development of the fetal respiratory system and the parallel development of the respiratory circulatory system detailed above in brief is not a guarantee of success for a newborn. Although structurally the systems may be sound and prepared for function, a newborn must also successfully transition from intrauterine life characterized by lungs filled with fetal lung fluid to extrauterine life characterized by lungs filled with air. During gestation, the fetus is supplied with oxygen-rich blood by the maternal circulation and placenta, thereby allowing most of the fetal circulation to be diverted away from the lungs via the ductus arteriosus. However, birth signifies not only a sudden introduction into the extrauterine world but also a severing of the connection to the placenta, thus creating a critical need for diversion of neonatal blood to the lungs as well as the capacity of the lungs to fill with air and begin the process of gas exchange at the alveolar capillary membrane. This has to occur immediately after birth to ensure survival (Table 1).

During fetal life, the lungs are filled with fetal lung fluid, distinct in composition from amniotic fluid. In fact, much of the mechanics of fetal lung expansion serve to reduce the amount of amniotic fluid in the lungs to as great an extent as possible, as it can be damaging to developing fetal lungs. Fetal lung fluid is actively secreted into the fetal lung air spaces by transcellular chloride transport, whereas clearance prior to birth (ideally) is mediated by active sodium absorption across the lung epithelium, described in greater detail below.

Table 1 Clinical lung abnormalities in newborns

Stage of lung development	Upper respiratory system	Lower respiratory system	Vasculature or muscle components
Embryonic state (3–7 weeks gestation)	1. Lung agenesis 2. Tracheoesophageal fistula (TEF)/esophageal atresia 3. Tracheal agenesis 4. Bronchogenic cysts 5. Intralobar sequestration 6. CPAM		
Pseudoglandular stage (5–17 weeks)	1. Extralobar sequestration 2. CPAM	1. Congenital acinar dysplasia	1. Congenital diaphragmatic hernia
Canalicular stage (16–26 weeks)		1. Surfactant deficiency (RDS) 2. Severe Bronchopulmonary Dysplasia (BPD) 3. Pulmonary hypoplasia (if low amniotic fluid levels)	1. Congenital alveolar dysplasia 2. Alveolar capillary dysplasia 3. Pulmonary hypertension
Saccular stage (24–38 weeks)		1. RDS 2. BPD 3. Transient tachypnea of the newborn (TTN)	1. Congenital alveolar dysplasia 2. Alveolar capillary dysplasia 3. Persistent pulmonary hypertension of the newborn (PPHN)
Alveolar stage (36 weeks and after)		1. TTN	1. PPHN

The distention of fetal lungs with fetal lung fluid is crucial to the appropriate development of the lungs and the volume of fetal lung fluid present is dependent on multiple factors including secretion of fetal lung fluid, fetal breathing movements, fetal position, fetal transpulmonary pressure, and amniotic fluid volume among some. Fetal breathing movements, reliant upon the fetal diaphragm, occur in conjunction with movement in the fetal laryngeal adductor muscles (which close off the airway). During periods of fetal apnea, these adductors actually function to protect the fetus against loss of fetal lung fluid by creating upper airway obstruction and a net efflux of fetal lung fluid that is less than the rate of fluid production whereas during periods of fetal breathing with diaphragmatic excursion there is a concomitant dilation of the glottis allowing a net efflux of fetal lung fluid (Wallace et al., 2017).

As you may expect from basic physics, the ability of fetal lungs to expand with fetal lung fluid volume is also dependent upon the physical environment in the uterus. If there are conditions causing decreased space for the fetus to fit, the fetus will experience a greater degree of flexion and therefore have less space for fetal lung expansion with fetal lung fluid. Conditions that can cause this include oligohydramnios (decreased amniotic fluid for a variety of reasons) and multiple gestation pregnancies.

While expansion with fetal lung fluid is crucial for lung development, at the time of birth, the fetal lung fluid must be cleared rapidly to allow for air entry and the initiation of gas exchange at the alveolar level. It was originally thought that fetal lung fluid clearance was primarily mediated by a squeeze mechanism induced by a neonate's passage through the birth canal. This was postulated as the reason that infants born by cesarean section delivery are at higher risk for delays in transition related to retained fetal lung fluid (transient tachypnea of the newborn or TTN). However, subsequent studies (both in animal models and by observation of human infants) demonstrated that while infants born by cesarean section without precedent labor do indeed have this elevated risk, those infants born by cesarean section following the initiation of labor have a similar reduction in fetal lung fluid as infants born by vaginal delivery (Carlton, 2017; Bland et al., 1979). Ineffective clearance of this fetal lung fluid can result in TTN, which is a temporary clinical respiratory problem stemming from retained fetal lung fluid and its impact on respiratory effort/function. For a summary of TTN and lung fluid clearance at birth see these reviews by Gugliani et al., 2008, 2009.

Surfactant

In addition to proper progression through the fetal developmental stages and appropriate expansion of the fetal lungs throughout gestation, the neonate must be able to generate appropriate surface tension to keep the alveoli expanded even between active breaths. Without this surface tension, distal airways will collapse between active inhalations leading to atelectasis (collapse of part of the lung) and respiratory distress. This surface tension is in large part achieved through surfactant, a phospholipid managed by alveolar epithelial type II cells. This management by type II cells involves not only production from precursors found in the circulation but also storage and recycling of surfactant to maintain a constant presence in the respiratory system. Surfactant is primarily composed of phospholipids, with dipalmitoyl phosphatidylcholine (DPPC) the most abundant. There are several types of surfactant proteins (SP) including SP-A, SP-B, SP-C, and SP-D and they have varying functions. SP-B and SP-C are the surfactant proteins that are physically associated with the phospholipids of lamellar bodies secreted into the airways. SP-B has the primary function of intercalating with surfactant phospholipid to reduce surface tension in the alveoli so that the alveoli remain open and do not collapse during the respiratory cycle (Whitsett and Baatz, 1992). SP-C appears to have a primary role in efficiently packaging the lipids into the multilayered lamellar bodies. Low amount of surfactant in the air spaces as a result of premature birth can lead to respiratory distress syndrome (RDS), another term for surfactant deficiency. On the other hand, genetic (hereditary) SP-B deficiency is most often lethal, whereas hereditary SP-C deficiency most often leads to nonlethal interstitial lung disease (i.e., progressive scarring of lung tissue, or fibrosis) (Nogee, 2004). Both SP-A and SP-D have significant roles in host innate immunity, important in helping the lung to fight off infections (McCormack and Whitsett, 2002).

Pulmonary Vasculature

The fetal development of pulmonary vasculature occurs alongside the development of the fetal lungs. Additionally, the diversion of the majority of fetal blood flow away from the lungs has been described. To review, oxygenation of fetal blood occurs in the placenta and this oxygenated blood is then returned to the fetus via the umbilical vein. The majority then bypasses the fetal liver via the ductus venosus, travels to the inferior vena cava and into the right atrium of the heart. At that point, rather than travel to the lungs, 90% of the blood is shunted across the foramen ovale to the left atrium to continue on to the left ventricle, or is shunted across the ductus arteriosus and out the aorta to supply blood to the body (Baldwin and Dees, 2012). Despite lower levels of oxygen in the fetal circulation, the fetus receives adequate oxygenation due to the increased concentration of fetal hemoglobin and its higher affinity for oxygen. Once birth occurs and the umbilical cord is cut, the newborn infant is dependent on gas exchange via the lung and the blood circulation can no longer bypass the lung. This is enabled by a drop in the resistance of the blood vessels in the lung, now inviting blood into the lung, to pick up oxygen and deliver carbon dioxide for disposal.

When studying the transition from fetal to neonatal life, there must be a discussion regarding the change in pulmonary vascular resistance that is required for successful transition. During gestation, there is high vascular tone maintained in the fetus due to the

action of vasoconstrictors such as endothelin-1 and platelet activating factor as well as low expression of vasodilators such as endothelium-derived nitric oxide and prostaglandin I₂. After birth, infants are exposed to room air (21% FiO₂) which is a significantly increased oxygen exposure than what infants experience in utero. This sudden change in environment from one of relative hypoxia (fetal environment) to one of relative hyperoxia (neonatal environment), as well as the initiation of respiratory ventilation, prompt a reversal which favors vasodilators over vasoconstrictors. The physical shear stress of the increase in blood flow suddenly traveling to the lungs also contributes to increasing vasodilation. There is a rapid decrease in pulmonary vascular resistance at birth but this decrease also continues over the first few months of postnatal life, before reaching normal adult levels others (Steinhorn and Abman, 2012; Gao and Raj, 2017). Additionally, ductus arteriosus closure occurs naturally in the first week of life as part of normal development, eliminating this as a shunt.

This transition becomes even more obvious in the setting of persistent pulmonary hypertension of the newborn (PPHN; previously known as persistent fetal circulation) in which the normal switch to a state favoring vasodilation does not occur at the time of birth. This can be an idiopathic disorder but more commonly is a result of chronic fetal hypoxia, pulmonary hypoplasia, sepsis, pneumonia, meconium aspiration syndrome, or RDS, among many other causes. The underlying etiology of the PPHN has a definite impact on the outcome and the therapies utilized to treat this disorder but PPHN is universally a disorder with high morbidity and mortality regardless of etiology.

Abnormalities in Development: Clinical Associations

Abnormalities that occur early in development most often affect the structural integrity of the initial developing large airways in the respiratory tract. Actual disruption in the development of lung buds from the primitive foregut can lead to pulmonary agenesis (absence of the lung altogether), with unilateral agenesis more common than bilateral agenesis. If the critical process of separation between the respiratory and the digestive tract does not occur properly in the first 6 weeks of gestation, this can result in the formation of a tracheoesophageal fistula (TEF), whereby there remains an abnormal connection between the two systems. There are several variations of this disorder but the most common is a blind pouch esophageal atresia proximally with a distal esophagus originating from the trachea. Tracheoesophageal fistulas can also be associated with multi-system congenital anomalies such as occur in the VATER/VACTERL association (acronym describing characteristics of the association: vertebral, anal, cardiac, tracheoesophageal, renal, and limb anomalies). Tracheal agenesis, while rare, can also occur in this stage with the trachea ending in a blind pouch and the main stem bronchi instead originating from the esophagus. TEF and tracheal agenesis are characterized by abnormalities in the separation of the respiratory tract from the primitive foregut. Similarly, additional budding from the primitive foregut can result in bronchogenic cysts, often in the mediastinal area. These are often fluid- or mucus-filled and do not usually communicate with the more distal airways. Rarely, abnormal budding from the ventral foregut can lead to the development of areas of abnormal pulmonary tissue, which can either be in connection with the lung (intralobar bronchopulmonary sequestration) or external to the lung (extralobar bronchopulmonary sequestration). Whether intralobar or extralobar sequestration develops is dependent on the timing of the abnormal budding from the foregut: intralobar sequestration occurs earlier, before lung pleura is formed, whereas extralobar sequestration occurs later leading to the development of its separate anatomy and separate pleura. Obstruction of portions of the larger airways can also result in congenital lobar overinflation through air trapping or in congenital pulmonary airway malformations (CPAMs) through abnormal branching morphogenesis (Wert, 2017).

In addition to disorders resulting from improper structural development of the large airways, there can be disorders in the development of the more distal airways, usually resulting in interstitial lung disease and pulmonary vasculature abnormalities such as pulmonary hypertension. These interstitial disorders include *congenital acinar dysplasia* which is a severe disorder characterized by deficiency in normal mature alveoli. This disorder likely occurs during the pseudoglandular stage of development. Growth arrest in the distal airways at later stages of gestation (such as the canalicular and saccular stages) may result in another severe disorder called *congenital alveolar dysplasia* in which distal airspaces are not properly approximated to the pulmonary vascular bed leading to dysfunctional gas exchange. In this disorder, there is sufficient development of the pulmonary vasculature; however it is not in close enough proximity to the distal airways to facilitate gas exchange. In comparison, *alveolar capillary dysplasia* is a disorder in which there are both insufficient pulmonary capillaries as well as poor proximity of the capillaries that do exist to the distal airways, compromising functional gas exchange. The pulmonary veins may also be located in an abnormal placement near the pulmonary arteries (misalignment of pulmonary veins) (Wert, 2017).

Developmental accidents involving other systems can also affect respiratory development and function. For instance, an error in the closure of the pleuroperitoneal fold in the pseudoglandular stage can result in an abnormal persistence of communication between the thoracic and abdominal cavities, allowing abdominal contents such as the stomach, bowel, and liver to herniate into the chest cavity (*congenital diaphragmatic hernia*). This space occupying mass of gastrointestinal structures results in compression of the developing lung and subsequent *pulmonary hypoplasia* with associated abnormal pulmonary vasculature development. Clinically, these infants have varying levels of respiratory failure and pulmonary hypertension depending on the severity and timing during gestation of the lesion, ranging from mild respiratory compromise to death. Pulmonary hypoplasia may also result from abnormal renal development, chronic amniotic fluid leakage, or upper airway obstruction. Each of these conditions result in decreased amniotic fluid and inadequate fetal lung fluid, which are crucial for lung development.

Finally, premature birth results in a growth disruption postnatally in both respiratory development and pulmonary vasculature development, with severity largely dependent upon the degree of prematurity. Infants born during the saccular stage of

development commonly have inadequate surfactant, resulting in surfactant deficiency at birth, called respiratory distress syndrome, or RDS. In addition, this lung developmental growth disruption affects many premature infants and can ultimately result in the chronic lung disease of prematurity called *bronchopulmonary dysplasia*.

Fetal Gastrointestinal Tract Development and Function

Norbert Chauvet, Sandrine Faure, and Pascal de Santa Barbara, University of Montpellier, Montpellier, France

Introduction

The vertebrate gastrointestinal (GI) tract is a vital and specialized organ system, located behind the body wall and characterized by its exceptional length. It is formed as a closed primitive tube that is regionalized during development along the anterior–posterior (AP) axis into various organs such as pharynx, esophagus, stomach (foregut), small intestine (midgut), and large intestine (hindgut) and specialized along the radial axis into concentric layers of morphological and functionally distinct cell types. These processes of differentiation according to different axes that are established during development and maintained throughout life are essential for the digestive tract to ensure its basic function, namely food digestion, absorption of nutrients and water, and elimination of feces (de Santa Barbara et al., 2002; Faure and de Santa Barbara, 2011).

Structural Anatomy and Function of the GI Tract

In adults, each part of the GI tract ensures different and complementary function (Fig. 1A). The stomach secretes acid and enzymes necessary for food digestion and possesses a hypertrophic muscular structure involved in the mechanical digestion of food. Conversely, the small intestine and colon have a thin muscular layer necessary for the transit and elimination of feces. Other functions ensured by the small intestine and the colon are the chemical digestion, absorption of nutrients and water, and the immune defense. Histologically, the adult GI tract is composed of four functional layers (mucosa, submucosa, muscularis propria, and adventitia or serosa). The mucosa is the innermost layer, in contact with the gastrointestinal lumen that harbor morphological features specific to each part of the GI tract; it is composed of epithelial cells with a supporting layer of connective tissue (the lamina propria) and a thin smooth muscle layer (the muscularis mucosae). Underneath the mucosa lays the submucosa, a sheet of loose connective tissue involved in its support. This is followed by the muscularis propria that is involved in the mechanical breakage of food intake, especially in the stomach, and is responsible for its transit along the AP axis by contracting in a phasic manner under the regulation of the autonomous enteric nervous system (ENS). Moreover, the GI tract is surrounded by the adventitia or serosa (depending on its AP position) to prevent frictions between the GI tract and other tissues/organs.

Development of the Fetal GI Tract

Origin and Patterning Along the Anterior–Posterior Axis (AP) During Early Development

The GI tract is a remarkably complex and specialized organ system derived from a primitive and undifferentiated tube that results from the association of the endoderm with the splanchnic mesenchyme at the early embryonic period. During gastrulation, the definitive endoderm ventrally invaginates to first give rise to the anterior intestinal portal (AIP) and secondly the caudal intestinal

Fig. 1 From AIP/CIP, to primitive to final GI tract. (A) Location of the adult GI tract into the body wall and its final organization into esophagus, stomach, small intestine, colon, and rectum following AP axis. (B) Formation of the primitive GI tube that harbors early AP regionalization divided into foregut, midgut, and hindgut. (C) Arrows show the anterior intestinal portal (AIP) and caudal intestinal portal (CIP) at the opposite poles of the embryo.

portal (CIP) ends of the embryo (Fig. 1C). These two structures elongate toward and fuse to form a straight and uniform primitive GI tube (Fig. 1B) (Roberts, 2000). The human primitive gut is formed at week 4 of gestation and is commonly divided in three embryological structures along the AP axis: foregut, midgut, and hindgut. The foregut will give rise to the pharynx, esophagus, and the stomach; the midgut will develop into the small intestine; and the hindgut will form the colon and the rectum. The foregut is the common embryonic organ that will give rise to two independent systems, the lung and gut. The respiratory system originates from the formation of an endodermal diverticulum in the ventral wall of the foregut, whereas the esophagus forms from the foregut dorsal wall (Faure and de Santa Barbara, 2011). The stomach also arises from the foregut and quickly starts to increase in size compare to the other parts of the primitive gut. The dorsal wall grows faster than the ventral wall, conducting to the stomach curvature. The primitive gut is localized in the coelomic cavity within the body wall and is connected to the dorsal mesentery. At week 6 of gestation, the length of the ileum rapidly increases and brings out part of the intestine. Between week 8 and 10, the intestinal loop rotates around the mesenteric artery and moves back into the coelomic cavity within the body wall. Finally, at week 11, the cecum moves downward, attracting the proximal part of the posterior intestine and the intestine reaches its adult final position. These regional morphological and functional differences are maintained throughout life and are essential for normal GI function.

Colonization of the Fetal GI Tract by the Enteric Nervous System (ENS)

Concomitant with the AP patterning, the GI tract is colonized by the enteric nervous system (ENS), the intrinsic innervation of the GI tract. The ENS is a complex intrinsic network of neurons and glial cells that controls gut motility. In human, it contains around 500 million neurons grouped in different subtypes (around 20 in humans) that differ in neurotransmitter expression, morphology, electrophysiology, and function (Gershon et al., 1993). All of the neurons and glial cells of the ENS are derived from the neural crest, a small population of cells that originate from the dorsal part of the embryonic neural tube (Fig. 2A) and migrate through a ventral route to colonize the developing GI tract (Fig. 2B). Chick and mouse models have contributed to our understanding of the origin and migration of the ENS. ENS precursors arise principally from two distinct regions. In the chick embryo, the vagal-derived progenitors enter the foregut mesenchyme on embryonic day 3 (E3) and begin an anterior to posterior wave of migration to populate the entire GI tract by E8.5 and establish its innervation (Le Douarin and Teillet, 1973). Additional crest-derived cells from the sacral region of the neural tube contribute to the postumbilical ENS progenitors that migrate in the opposite direction through the distal hindgut (Burns and Le Douarin, 1998; Wang et al., 2011) (Fig. 3A). In addition, when colonizing the stomach and the intestine, the migration front of ENS cells is located in the outermost layer of the mesenchyme, adjacent to the serosal epithelium and will migrate inwards to set up plexuses (Fig. 3B) (Burns and Le Douarin, 1998). In contrast, in the colorectum area, ENS cells initially colonize the submucosal layer before migrating outwards to organize the myenteric plexus (Fig. 3B) (Burns and Le Douarin, 1998). To form the human ENS network, precursors must migrate away from the esophagus at week 4 of gestation and spread uniformly throughout the entire bowel, proliferate and undergo sequential lineage restriction to reach the colon at week 7 of gestation before differentiating into many distinct subtypes of interconnected neurons and glia that become organized into enteric ganglia that comprise the myenteric (Auerbach') and submucosa (Meissner') plexi located between the muscle layers of the gut wall (Grundty and Schemann, 2005; Furness, 2006). Contribution of a sacral neural crest pool to the ENS in humans remains unknown. The end result of all this developmental process is the formation of an integrated neuronal network, which controls visceral smooth muscle cell contractions (or peristalsis) and GI motility to ensure food transit.

Late Development: Differentiation of Fetal Into Functional GI Tract

The differentiation of intestinal mesoderm into intestinal smooth muscle occurs also along the radial axis and is conserved in all vertebrates as indicated by the expression of alpha-smooth muscle actin (alpha-SMA) as marker (Fig. 4) (Le Guen et al., 2015; Shyer et al., 2013). At week 7 of gestation, the primitive gut is a simple tube with a stratified undifferentiated endodermal layer that is surrounded by an undifferentiated and uniform mesenchymal layer, in which few alpha-SMA positive cells are present at the periphery of the mesenchyme. In addition, interstitial cells of cajal (ICCs) emerged from the developing gut mesenchyme at

Fig. 2 Origin of the enteric neural crest cell derived cells. (A) After the closure of the neural tube in the trunk of the chick embryo, the vagal neural crest cells (NCCs) emigrate through the neural tube at Stage 11 (E2). (B) Vagal NCCs migrate to the anterior portion of the sclerotome at Stage 14 (E2.5). (C) Vagal NCCs enter into the GI tract at Stage 18 (E3) through invading the anterior foregut mesenchyme.

Fig. 3 Colonization of the GI tract by the autonomous ENS from vagal and sacral neural crest origins. (A) Vagal neural crest cells (NCC) adjacent to somites 1–7 colonize the whole GI tract in an anterior-to-posterior direction during days E3–9. Sacral NCC caudal to somite 28 migrate in a - posterior-to-anterior direction to form first the nerve of Remark adjacent to the gut wall during days E4–6 and enter in the gut after E10. (B) Within the preumbilical small intestine, vagal NCCs initially migrate within the outer mesenchymal region, then migrate inwards to colonize the submucosal plexus region. Within the colorectum, vagal NCCs initially migrate within the submucosal region, then migrate outwards to colonize the myenteric plexus region. In addition, after their migration and stop through the Nerve of Remark, within the hindgut, sacral NCC colonize the myenteric plexus region, then migrate inward, to colonize the submucosal plexus.

Fig. 4 Development and differentiation of the intestinal SMCs. Smooth muscle cell differentiation in the small intestine of chicken embryos. Smooth muscle cells (SMC) were detected by immunostaining with an antibody against the SMC-specific marker alpha-SMA (brown color), before their transformation into cartoons. (A) Nonorganized and undifferentiated mesenchymal cells in the small intestine of a 6-day-old (E6) chick embryo. During early embryonic development, the visceral endoderm is uniform with stratified layers of cells. (B) alpha-SMA-positive cells in the circular smooth muscle layer of the small intestine of an E13 chick embryo. The ongoing intestinal epithelial cytodifferentiation leads to the formation of an epithelial monolayer. (C) alpha-SMA-positive cells in the longitudinal and circular smooth muscle layers of the small intestine of an E15 chick embryo. (D) alpha-SMA-positive cells in the longitudinal, circular, and submucosal smooth muscle layers in the small intestine of an E16 chick embryo. (E) alpha-SMA-positive cells (myofibroblasts) are detected also in the lamina propria of the small intestine in an E18 chick embryo. (C–E) Intestinal epithelial cytodifferentiation is marked by mesodermal growth into the lumen and villi formation, characterized by specific long and thin villi in the small intestine. *csm*, circular smooth muscle; *lsm*, longitudinal smooth muscle.

week 9 to surround and closely oppose the myenteric ganglia by week 11 to participate to the electrical pacemaker activity of the gut (Wallace and Burns, 2005). The stratified, undifferentiated endodermal cells undergo a columnar transformation accompanied by mesodermal outgrowth. This process results in the development of villi (starting at about week 9 of gestation) along a cranial to caudal axis. A differentiating external circular muscle layer is also observed. The anterior–posterior axis influences the morphologic and epithelial cell differentiation along the radial axis as well.

Hence, in late fetal life, the small intestine epithelium is characterized by long and thin villi, whereas the colon epithelium shows wide and flat villi (Fig. 5) (de Santa Barbara et al., 2003). Villi are separated by a proliferating intervillus epithelium. As the gut develops the intervillus epithelium is reshaped downwards to form crypts. At around week 12–14, primitive crypts begin to appear and at week 13, both circular and longitudinal muscularis can be observed. At week 16, the muscularis mucosa appears and is fully organized by gestational week 18. By week 20, the intestine displays well-developed villi and crypts supported by a specialized connective tissue (the lamina propria), where some alpha-SMA positive cells (myofibroblasts) are observed. The crypt-villous unit allows for a great increase in the surface area for absorption. The small intestine conserves its villus-crypt units throughout life. Conversely, in the adult colon of many species (including humans, but not chickens), embryonic villi will disappear. Transient formation of villi is observed in the embryonic proximal part of the colon, but in humans these villi are flattened before birth and thus the adult human colon is characterized by a relatively flat epithelium regularly separated by crypts. The formation of these crypt-villous structures and epithelial cell differentiation rely on reciprocal signaling between endoderm and mesoderm that occurs during early development period.

Reciprocal Interaction During the Fetal GI Tract Development

In most vertebrates the intestinal endoderm shows a uniform morphology (undifferentiated and stratified cuboidal cells) until mid-gestation when epithelial–mesenchymal interactions direct endodermal differentiation. Signals provided by the mesoderm/smooth muscle will first regulate AP regionalization during endoderm patterning/differentiation, but also will secondarily participate to the epithelium shaping and villi formation. The mature gut epithelia conserve their morphologic and functional pattern specificities throughout adult life.

Mesenchyme–Epithelial Interaction in AP Patterning

After AIP and CIP fusion, the GI endoderm is uniform along its AP axis. However, as differentiation takes place, morphological differences appear, leading to the formation of region-specific epithelium types. These mechanisms involve reciprocal (bi-directional) signals between epithelial cells and the adjacent mesoderm that are required for normal homeostasis. Many studies have demonstrated the importance of the interactions between endoderm and mesoderm during early GI tract development. In vitro experiments have demonstrated that the primitive foregut endoderm needs to be co-cultured with heterologous splanchnic mesenchyme to allow the correct differentiation along the AP axis, while somitic or cephalic mesoderm and limb buds are relatively inefficient. This finding supports the idea that the actors governing the regionalization of digestive epithelia are specifically found in the splanchnic mesenchyme. Many studies reported evidence that in the gut, the mesoderm dictates the ultimate epithelial pattern. For instance, in chicken embryos, early muscular stomach (gizzard) endoderm co-cultured with glandular stomach (proventriculus)

Fig. 5 From development to differentiation of the intestinal epithelium. During early embryonic development, the visceral endoderm appears as a uniform, stratified cell layer. Intestinal epithelial differentiation occurs during fetal development and is marked by mesodermal growth toward the lumen and formation of villi that are separated by proliferative intervillus epithelium. Anterior–posterior axis morphological differences appear: long and thin villi in the small intestine and transitory wide, flat villi in the colon. The intervillus epithelium of the small intestine is reshaped downwards to form crypts. In humans, the final architecture of the small intestine is reached before birth and is characterized by the crypt-villous unit. The colonic villi disappear at the time of birth and the mature colon epithelium present tubular glands (crypts). Modified from de Santa Barbara et al. (2003). Development and differentiation of the intestinal epithelium. *Cellular and Molecular Life Sciences* 60(7), 1322–1332.

mesoderm differentiates into proventricular epithelium (Kedinger et al., 1998). However, there is one exception to the endoderm morphological/cytological plasticity upon exposure to regional-specific mesoderm. Indeed, co-culture of midgut epithelium with heterologous mesenchymal tissues does not influence its specification, as indicated by the retained expression of midgut epithelial digestive enzymes (Kedinger et al., 1998). This difference in the ability of midgut and foregut endoderm to undergo complete heterologous differentiation demonstrates that the mechanisms involved in the gut epithelium cyto-differentiation are different along the AP axis, with midgut endoderm displaying cell-autonomous features.

Reciprocal Interaction Between Enteric Nervous System and Smooth Muscle/Mesenchyme

Interaction of ENS cells with mesenchymal/smooth muscle layer are necessary for their correct migration and differentiation (Burns and Le Douarin, 1998). Moreover, coordinated smooth muscle differentiation and ENS migration are required for normal GI development and patterning. The specific deletion of ENS cells into the stomach impairs smooth muscle development and induces trans-differentiation of both stomach mesenchymal and epithelial layers into a mixed stomach–intestine structure (Faure et al., 2015), supporting a multiple tissular interaction requirement for correct stomach development and differentiation. If the differentiation of the smooth muscle cells of the stomach require the presence of a crucial number of ENS cells, early intestinal smooth muscle differentiation is required for patterning the developing ENS (Graham et al., 2017), demonstrating the difference of mesenchymal/ENS interaction process along the developing GI tract.

Reciprocal Interaction During Smooth Muscle Cell Differentiation and Epithelial Organization

As above commented, during the embryonic period the digestive mesenchyme differentiates into radial axis forming distinct concentric layers around the epithelium: the lamina propria, muscularis mucosae, submucosa, and the smooth muscle layers. Endodermal-derived signals are responsible for the patterning across the radial axis of the gut (Sukegawa et al., 2000). In addition, when skin fibroblasts or somitic mesoderm are co-cultured with gut endoderm, they differentiate into smooth muscle rather than fibroblasts or skeletal muscle through the induction of the expression of smooth muscle marker, such as alpha-SMA (for review, Le Guen et al., 2015). Moreover, epithelial morphogenesis and villus formation of the gut is intimately linked to the sequential differentiation of the three smooth muscle layers, which produce a series of different mechanical forces. Treatment of the intestinal tube with inhibitors of smooth muscle differentiation prevents these progressive villus patterning. Thus, the compressive forces from the smooth muscle layers drive the epithelium to buckle and fold to finally form villus structures (Shyer et al., 2013). Indeed the formation of villi generates gradients of morphogen signaling that restrict the stem cells within the crypt to the base of each villus (Shyer et al., 2015).

Conclusion

As described, the complex and functional pediatric GI tract originates from the lateral splanchnic mesoderm that contributes to the intestine mesoderm and overlays the endoderm to form the primitive intestine. During their development, differentiation and morphogenesis, these structures are colonized by neural crest-derived cells that will form the ENS to participate to the network essential for the peristalsis. Moreover, during development the digestive mesenchyme is also colonized by other cell types such as endothelial and lymphatic cells (Hatch and Mukouyama, 2015). In addition, serosal mesothelial cells also colonize the entire primitive gut and a subset of these cells undergoes epithelial–mesenchymal transition to differentiate into smooth muscle cells that surround the primitive vessels formed by endothelial cells (Wilm et al., 2005; Kim et al., 2007). Intestinal vascular and lymphatic networks serve as efficient nutrient and lipid absorption.

In the neonatal and adult GI tract, multicellular interactions are essential for the development but also for the maintenance of the regionalization and homeostasis of the GI tract. Disruption of these interactions is also associated with bowel malformation or dysfunction, such as tracheo-esophageal atresia (TE), infantile hypertrophic pyloric stenosis, or anal atresia (Faure and de Santa Barbara, 2011; de Santa Barbara et al., 2002).

Summary

This article describes the development and the multitissular interaction mechanisms that drive the differentiation of the fetal gastrointestinal (GI) tract to ensure correct morphogenesis and its basic function. We pass through the anatomy and function of the adult GI tract before focusing on the development of the primitive and fetal GI tract. We describe the early patterning and the late differentiation of the fetal GI tract, its colonization by the enteric nervous system and the reciprocal multilayer interactions to ensure early patterning, late differentiation, and epithelial organization. Finally, we conclude by showing the importance of these events to achieve the normal and functional digestive system.

Germ Cell Sex Differentiation

Kellie S Agrimson, University of Minnesota, Minneapolis, MN, United States

Cathryn A Hogarth, Washington State University, Pullman, WA, United States

© 2018 Elsevier Inc. All rights reserved.

Overview

The germ cells of both sexes arise from the primordial germ cells (PGCs) that are specified in the mouse epiblast at E6.25 and migrate to the embryonic gonad by E10.5. Germ cell sex is determined by the somatic environment of the gonad which is made up of either Sertoli (testis) or granulosa (ovary) cells, based on the presence or absence of SRY expression, respectively. While germ cell sex determination occurs in response to the somatic environment, germ cell sex differentiation depends on the levels of retinoic acid (RA) present in the gonad. PGCs in the fetal ovary are triggered to become oogonia and enter meiosis, arresting at the diplotene stage of meiosis I just prior to birth. Male PGCs continue to proliferate both prior to and after birth in the testis, separated by a period of cell cycle arrest, and enter meiosis asynchronously from puberty onward (**Fig. 1**). This article will discuss the field's current understanding of mouse germ cell sex differentiation and the role of RA during germ cell meiotic entry. To understand how RA plays a role in germ cell differentiation, first the intricacies to the RA signaling pathway must be explored.

How Is Retinoic Acid Metabolized in the Gonads?

Transport and Storage

Vitamin A, accumulated through the diet, is transported through the circulatory system in the form of retinol. Retinol binding proteins mediate retinol delivery to target organ systems in the body and once retinol reaches the cell, it is either stored as retinyl ester or metabolized into RA, the active metabolite of vitamin A (**Fig. 2**).

Synthesis

A two-step oxidative process converts retinol to RA. The first reversible step forms retinal from retinol via the action of the retinol dehydrogenases (RDH) or short chain dehydrogenases (DHRS), while the irreversible second step occurs when aldehyde dehydrogenases (ALDH) oxidize retinal into RA (**Fig. 2**). Depending on the tissue, there are varying isoforms of the oxidizing enzymes with fluctuating levels of activity necessary for the production of RA. Therefore, the expression patterns of the isoforms may differ within a single tissue which allows for RA levels in an organ system to be tightly controlled. The RDH and ALDH enzymes have been most well studied within the testis, while very little is known about their role in female germ cell development.

Degradation

RA has two fates in a cell, one of which is being catabolized into inactive metabolites by the cytochrome p450 family 26 (CYP26) enzymes, including three isozymes: CYP26A1, CYP26B1, and CYP26C1 (**Fig. 2**). RA degradation in a cell occurs in order to block or stop the expression of RA-responsive genes or to protect a neighboring cell from exposure to this signal. CYP26A1 and CYP26B1 are both expressed within the testis and are essential for the normal progression of spermatogenesis (**Hogarth et al., 2015**). Additionally, the current published data suggest that germ and Sertoli cells are protected from external RA signals by the peritubular myoid cells that surround the seminiferous epithelium based on the localization of *Cyp26* mRNA (**Vernet et al., 2006b; Wu et al., 2008**). As a result, RA levels within the seminiferous epithelium are likely regulated by cross-talk between germ and Sertoli cells.

Signaling

The other fate of RA is to control gene expression by RA receptor (RAR)/retinoid X receptor (RXR) mediated signaling. RA bound to a heterodimer of RAR/RXR can interact with RA response elements (RAREs) within gene regulatory regions (**Bastien and Rochette-Egly, 2004**). Recruitment of coactivators or corepressors control gene activity. In the absence of RA, RAR/RXR bound to RAREs recruit histone deacetylase complexes (HDAC) to repress gene expression. Once RA is bound, the HDAC is released and the RA/RAR/RXR bound complex will recruit histone acetylases or methyltransferases to open chromatin and activate gene expression. Both RAR and RXR families have three different isoforms including α , β , and γ . To date very little is known about the specificity and function of the RAR/RXR receptors in the ovary. However, Sertoli cell expression of RAR α and RXR β and germ cell expression of RAR γ are known to be required for proper spermatogenesis (**Gely-Pernot et al., 2012; Vernet et al., 2006a, 2008**).

How Are Male and Female Germ Cell Paths to Meiotic Entry Different?

Female germ cell entry into meiosis occurs embryonically in response to RA, while male entry occurs after birth in the mouse. RA synthesis occurs in the mesonephros of the developing urogenital ridge and then, in an anterior to posterior direction, moves into

Fig. 1 Timeline summarizing the period of mouse PGC specification through sex determination and germ cell sex differentiation. By E11.5 sex is determined and germ cell fates diverge based on whether the surrounding gonad is male or female. The Sertoli cells express CYP26B1, which degrades any RA present in the testis and protects the male prospermatogonia from entering meiosis prematurely. In contrast, the ovary stops expressing CYP26B1 by E12.5, allowing oogonia to respond to active RA signaling. These oogonia express STRA8 and enter meiosis prior to birth. Male germ cells do not enter meiosis until after birth following spermatogonial differentiation in response to RA and several rounds of proliferation. Spermatogonia enter meiosis as preleptotene spermatocytes in response to STRA8 expression induced by RA signaling.

Fig. 2 Network of RA metabolizing enzymes and their role in RA synthesis and degradation. Retinol, transported through the body in the circulatory system, can either be stored as retinyl esters or converted to retinal, both of which are reversible reactions. Lecithin retinol acyltransferase (LRAT) converts retinol into retinyl ester while retinyl ester hydrolase (REH) mobilizes retinyl ester into retinol. Retinol is reversibly converted into retinal by the retinol dehydrogenases (RDH) or short chain dehydrogenases (DHRS). Retinal is irreversibly oxidized into RA by the aldehyde dehydrogenases (ALDH). RA can then signal within cells through the RAR/RXR mediated pathway or be degraded into inactive metabolites by the cytochrome *p*450 family 26 (CYP26) enzymes.

the ovary or testis via the mesonephros ducts at approximately E11.5. However, by this time the Sertoli cells have surrounded the germ cells within the testis cords and express CYP26B1, protecting the male germ cells from the RA signal. CYP26B1 acts as the meiotic inhibitory factor and degrades RA in the fetal testis. In contrast CYP26B1 expression is lost in the ovary by E12.5 and RA from the mesonephros induces female germ cells to express Stimulated by RA 8 (STRA8) and enter into meiosis (Fig. 3). The remaining sections of this article will examine what is known about female and male meiotic entry based on data collected from transgenic mouse gene knockout models and manipulations of RA levels in the gonads.

STRA8

STRA8 is currently described as the “gatekeeper” to meiosis. The regulatory region of *Stra8* includes two RAREs that are targeted directly by RA and STRA8 expression can be detected in as little as 2 h following RA exposure (Evans et al., 2014; Giuili et al.,

Fig. 3 Hypothesized roles for RA metabolic enzymes in the fetal testis and ovary. (A) CYP26B1, present in the Sertoli cells of the testis cords, degrades RA that is synthesized in the mesonephros by ALDH enzymes and diffuses into the testis in an anterior—posterior direction. RA degradation is shown in this model by the red X marks in the testis. (B) CYP26 is not expressed in the fetal ovary after E12.5, therefore allowing oogonia to turn on STRA8 and enter meiosis. This occurs in an anterior—posterior direction, shown by oogonia transitioning from red to yellow in this model. Additionally, some ALDH expression has been recently reported to be present in the fetal ovary, although likely only highly expressed when having to compensate for loss of other ALDH isoforms.

2002; Oulad-Abdelghani et al., 1996). *Stra8* deficiency results in infertility as meiosis is unable to initiate (Baltus et al., 2006). In the absence of *Stra8*, premeiotic DNA replication, meiotic chromosome condensation, cohesion, synapsis and recombination do not occur in female fetal germ cells (Baltus et al., 2006). Although the exact function of STRA8 is unknown, global deletion of *Stra8* resulted in misregulation of REC8, SYCP3, and H2AFX, all of which are meiotic markers. Ovary size was significantly reduced as were oocyte and follicle numbers (Dokshin et al., 2013).

How Does Deletion or Inhibition of the ALDH1A Synthesizing Enzymes Affect Germ Cell Differentiation?

Until recently, there was controversy over whether or not RA drives female germ cell meiotic entry. Past work investigated female meiotic entry in *Aldh1a2*- and *Aldh1a2/Aldh1a3*-deficient mice to examine the necessity of RA (Kumar et al., 2011). Pregnant mice carrying these ALDH deficient embryos were supplemented with RA from E6.75 to E9.25 to prevent embryonic lethality, as *Aldh1a2/Aldh1a3*-deficiency is embryonic lethal because these embryos do not synthesize enough RA to complete early embryogenesis. This brief supplementation allowed Kumar et al. (2011) to examine the effects from deficiencies following sex determination. RA has an extremely short half-life and the supplemental RA given to the pregnant females was cleared within 12–24 h (Mic et al., 2002). Surprisingly, *Stra8* expression was detected in oogonia deficient in *Aldh1a2/Aldh1a3* and additionally *Sycp3* and H2AFX were expressed in oogonia deficient in *Aldh1a2* alone (Kumar et al., 2011). The idea that the ovary may express a synthesizing enzyme was dismissed due to results collected from *RARE-hsplacZ* reporter transgene mouse model bred to the ALDH mutant mice (Rossant et al., 1991). This mouse model allows for visualization of active RA signaling within individual cells. Kumar et al. (2011) found that the urogenital ridge, not the ovary, expressed β -galactosidase. Although this transgene has been known to lose activity (Sakai and Drager, 2010) and it is possible that the breeding of this reporter line into the different genetic background of the ALDH mutant could have disrupted the expression of the transgene. Based on these results, Kumar et al. (2011) concluded that meiotic initiation can take place in the ovary without RA. However, more recently Bowles et al. (2016) found that *Aldh1a1* is expressed and produces RA in the developing ovary and that *Aldh1a1* expression is sensitive to RA levels in the developing gonads. This would suggest that in the previously discussed *Aldh1a2/Aldh1a3* knockout mouse model the amount of ALDH1A1 available to stimulate germ cell meiosis by synthesizing RA might have been enhanced (Bowles et al., 2016). As a result, it is likely that RA is required for female oogonia to enter meiosis.

RA deficiency can be achieved via either chemical inhibition of ALDH activity using the compound WIN 18,446, an irreversible inhibitor of ALDH1A2 and a reversible inhibitor of ALDH1A1 and ALDH1A3 (Arnold et al., 2015a, b), or by restricting vitamin A levels in the diet and thereby making the mice vitamin A deficient (VAD) and blocking the substrate necessary for RA synthesis. Oogonia from VAD female rat embryos exhibited a lack of *Stra8* expression and never initiated meiosis (Li and Clagett-Dame, 2009) suggesting the necessary role of RA in meiosis. Additionally, treatment of female urogenital ridges with WIN 18,446 resulted in blocked *Stra8* expression in oogonia (Hogarth et al., 2011). Taken together, these data suggest that meiosis does not initiate in RA deficient ovaries (Fig. 4).

How Does Deletion or Inhibition of the CYP26 Degrading Enzymes Affect Germ Cell Differentiation?

Examination of fetal *Cyp26b1* null testes in culture with RARE reporter cells revealed threefold higher RA levels when compared to control littermates (MacLean et al., 2007). Additionally, a significant reduction in germ cell number due to apoptosis and testis size at birth occurred (MacLean et al., 2007). The remaining germ cells left in *Cyp26b1* mutant testes had entered meiosis and some progressed as far as the pachytene stage of prophase I (MacLean et al., 2007).

More convincingly, Sertoli cell-specific deletion of *Cyp26b1* using the *Amh*-Cre revealed that germ cells in G0 reentered the cell cycle and initiated meiosis (Li et al., 2009). These studies support RA as the trigger for meiotic entry in the fetal gonad and provide

Fig. 4 Hypothesized model displaying loss of ALDH activity in the female urogenital ridge either by gene deletion or protein inhibition. In fetal ovaries that are not exposed to RA, oogonia do not express STRA8 or enter meiosis shown by red oogonia in the mutant compared to yellow differentiating oogonia in the control ovary. Red X marks in the mutant show loss of ALDH activity in the female urogenital ridge.

Fig. 5 Hypothesized model representing loss of CYP26 activity in the male urogenital ridge either by gene deletion or protein inhibition. In fetal testes that lose CYP26B1 activity, the Sertoli cells are unable to protect prospermatogonia from prematurely entering meiosis displayed by the mutant testis cords that have germ cells expressing STRA8 shown by *yellow* cords compared to *blue* cords in the control testis. Loss of CYP26B1 activity is represented by the *red X* marks in the testis.

evidence to suggest that the Sertoli cell population acts as a protective barrier for male prospermatogonia (Fig. 5). Interestingly dual knockout of *Cyp26b1*/*Stra8* male embryos rescues this phenotype (Saba et al., 2014). When STRA8 is unable to be expressed, prospermatogonia fail to enter meiosis (Saba et al., 2014). This observation further supports the notion that STRA8, in response to RA, is required for meiotic prophase initiation in both sexes.

Additional evidence to suggest that the CYP26 enzymes are crucial to RA degradation and preventing male germ cells from entering meiosis in the fetal testis was collected in studies using two chemical inhibitors. Ketoconazole, nonspecific cytochrome *p*450 inhibitor, and talarozole (R115866), CYP26-specific inhibitor, were used in separate studies to treat mouse male urogenital ridges in ex vivo organ cultures (Bowles et al., 2006; Koubova et al., 2006; Piprek et al., 2013). In both cases prospermatogonia precociously expressed *Stra8* and other markers of meiotic initiation.

How Does Altering Ra Signaling Affect Germ Cell Differentiation?

RA was first implicated in playing a role in female meiotic entry when rat female ovaries were exposed to exogenous RA and initiated premature meiosis (Livera et al., 2000). Additionally, treatment with a RAR α agonist drove meiotic initiation in female oögonia suggesting that stimulation of the RA signaling pathway also can drive germ cells into meiosis (Livera et al., 2000). Although male prospermatogonia did not respond to physiologically relevant levels of exogenous RA, likely due to normal CYP26B1 activity (Kumar et al., 2011).

Female urogenital ridges that were treated in culture with two different RAR panantagonists, BMS-204493 and AGN193109, did not express *Stra8* and other key meiotic markers to the same level as controls (Bowles et al., 2006; Koubova et al., 2006). This suggests that disrupting the RA signaling machinery alters oögonia meiotic initiation and further supports a role of RA in female germ cell differentiation. Further genetic studies are needed to more clearly understand the role of each isoform of RAR and RXR during meiotic initiation in the female germ cell. However, the redundancy between receptors may pose problematic when trying to tease out specific receptor functions.

Conclusions

Taken together, these data would suggest that RA signaling and STRA8 expression are essential for the normal progression of female germ cell meiotic entry, while fetal male testes protect their germ cells via degradation of RA by the expression of CYP26 enzymes within Sertoli cells. In this article, evidence was provided to demonstrate how female and male germ cells differentiate in response to endogenous RA levels. Further, manipulating RA levels in both male and female fetal gonads affected the normal progression of germ cell differentiation. Altering RA synthesis via ALDH1A enzymes prevented the expression of meiotic markers in the fetal ovary, while disrupting RA degradation through the CYP26 enzymes induced germ cell meiotic entry in male fetal testes. Further work will need to be performed to definitively pinpoint RA as the meiotic inducing factor, and these studies must include measuring RA concentrations without using a transgenic reporter and genetically breeding the triple *Aldh1a* knockout mouse.

GERMLINE EPIGENETIC INHERITANCE

Genetic Vs. Epigenetic Inheritance Overview

John R McCarrey, University of Texas at San Antonio, San Antonio, TX, United States

Inheritance

Inheritance refers to the transmission of traits from one generation to the next or from one parent cell to two daughter cells. In a broad sense of the word, inheritance can refer to the persistence of any characteristic that is observable in parents or parent cells that is also observed in offspring or in daughter cells, respectively. Typically, however, inherited characteristics result from the transmission of specific information that can be encoded at the molecular level and transmitted as such from one generation to the next or from one cell to the next. There are two general types of information encoded at the molecular level. One involves information encoded at the level of the base sequence associated with nucleotides in double-stranded DNA, and this is referred to as *genetic inheritance*. The other involves information encoded as chemical modifications of DNA or chromatin, and this is referred to as *epigenetic inheritance*. Inheritance of either genetic or epigenetic information requires propagation of the relevant base sequence or pattern of DNA or chromatin modifications, respectively, throughout the process of DNA replication. Genetic information is typically quite stable, becoming changed only as a result of mutations, or by the physical rearrangements that can occur as a result of meiotic recombination. Epigenetic information is often less stable. The epigenome is different in every cell type and undergoes changes—typically referred to as reprogramming—during each generation. By definition, epigenetic information is reversible, and so is more labile than genetic information. Nevertheless, both genetic and epigenetic information are encoded by molecular mechanisms, and each can be transmitted from generation to generation or from parent cell to daughter cell on the basis of specific molecular mechanisms responsible for the transmission of the respective forms of encoded information.

Genetic Inheritance

Classically, the heritable transmission of traits is dependent upon genes, and in most species, genes are maintained as sequences of double-stranded deoxyribonucleic acid (DNA). This is the basis for *genetic inheritance*. Each strand of DNA is a polymer (chain) of nucleotides that each include one of four different bases—thymine (T), guanine (G), cytosine (C), or adenine (A). Each nucleotide in one strand of the DNA double helix is paired with a complementary nucleotide in the other strand of the double helix. This pairing follows base pairing rules, such that adenine is always paired with thymine (= an “A–T base pair”), and cytosine is always paired with guanine (= a “C–G base pair”). Genetic inheritance refers to the propagation of DNA sequence from one generation to the next or from a parent cell to a daughter cell.

Before cells divide by mitosis, they must first replicate their DNA. This replication process faithfully transmits identical copies of the double-stranded DNA sequence found in the parent cell to each of two daughter cells. DNA replication is a semiconservative process, in that the two strands of the DNA double helix found in the parent cell separate and each acts as a template for synthesis of a new, complementary strand. Because of the base pairing rules, the specific base associated with each nucleotide added to the new DNA strand is dictated by the complementary base present in the template (old) DNA strand. Thus, if a nucleotide with a C is present in the old DNA strand, it will template the addition of a nucleotide with a G during synthesis of the new strand. Similarly, a G or a T or an A in the old/template strand will dictate the addition of a complementary C, A, or T base in the newly synthesized strand. In conjunction with proofreading functions associated with DNA replication, as well as DNA repair mechanisms that function in response to various types of damage incurred in the base sequence in DNA, the DNA sequence is maintained as a relatively stable entity throughout all phases of the cell cycle and is faithfully propagated from generation to generation or parent cell to daughter cell. Genetic inheritance is responsible for the conservation of genetic information among all cell types in the body, as well as that within a pedigree, or among individuals within a particular species or even among related species. As such, genetic information provides the “hard wired” information that forms the essence of each species and of each individual within a species.

Epigenetic Inheritance

Epigenetic inheritance represents the transmission of information that *regulates* the function of the genetic information (i.e., of the genome). All cells within a multicellular individual typically inherit the same genetic information/genome/DNA sequence, yet different cell types become differentiated from one another on the basis of differential expression of the genetic information common to all cell types. Further, each different cell type normally emerges in the correct position within the body and adopts

the correct function(s) associated with the tissue and/or organ in which it is found. This requires that the development of each specific cell type, tissue or organ is highly regulated in a specified and coordinated manner so that all cells within any tissue or organ will function either identically or in a coordinated manner, and this process is regulated by epigenetic information. This is achieved by regulating gene expression. Epigenetic mechanisms regulate the structure of chromatin, and/or they regulate the affinity of genes for specific types of regulatory factors.

Typically, a gene, or at least the promoter plus transcriptional start site of a gene, need to be associated with relatively decondensed (open) chromatin structure to facilitate the process of transcription. Initiation of transcription requires the association of a transcription complex containing RNA polymerase plus associated factors with the gene promoter which will induce a transient, localized denaturation (separating) of the double helix so that one of the two DNA strands can serve as a template for transcription. The requisite transcription complex plus associated factors needed to initiate transcription of a particular gene can be present in the nucleus of a cell but if they are unable to associate with/bind to the promoter of that gene, no initiation of transcription will occur. Thus, regulation of chromatin structure can regulate gene expression, and epigenetic regulators can control the status of chromatin structure.

Epigenetic information occurs in the form of covalent modifications of DNA and/or chromatin. Examples include methylation of DNA. Specifically, in mammals, cytosines present in CpG dinucleotides (= a C-bearing nucleotide followed by a G-bearing nucleotide side by side in a 5' to 3' orientation of a single DNA strand can become methylated at the 5 carbon position = 5-methyl cytosine). Alternatively, but not mutually exclusively, proteins associated with DNA—particularly the core histones that make up nucleosomes that associate with DNA (H2A, H2B, H3, or H4) can undergo modifications including methylation, acetylation, phosphorylation, and/or other post-translational modifications at specific amino acid residues, and this will influence the affinity of the interactions between DNA and the nucleosomes or the interactions between neighboring nucleosomes and this, in turn, will affect overall chromatin structure and gene expression. Specific molecular mechanisms regulate the faithful propagation of these epigenetic modifications such that the associated effects on gene expression are transmitted from a parent cell to its daughter cells. Thus, patterns of DNA methylation are propagated by maintenance methylation. Because a 5'-CpG-3' dinucleotide on one DNA strand will be paired with a complementary 5'-CpG-3' dinucleotide on the other DNA strand, a fully methylated DNA site will include methylation of the cytosines on both strands. When this fully methylated site undergoes semi-conservative DNA replication, each existing, methylated strand will template synthesis of a new complementary strand that is initially unmethylated. However, this "hemimethylated" site is then recognized by the maintenance DNA methyltransferase which adds a methyl group to the unmethylated C such that the site is returned to a fully methylated state. If the same sequence is completely unmethylated when it undergoes DNA replication, no hemimethylated state will be achieved and the unmethylated site will be propagated as such. Thus, while the base sequence of a gene is transmitted via genetic inheritance, the epigenetic modifications associated with that gene are transmitted via epigenetic inheritance. Although not as thoroughly understood, existing evidence suggests that a similar mechanism contributes to propagation of histone modification patterns throughout the process of DNA replication.

Summary

Genetic inheritance refers to the transmission of DNA sequence information, whereas epigenetic inheritance refers to the transmission of patterns of modifications to either DNA or chromatin. These two mechanisms operate simultaneously. As a result, the same set of genetic information can be propagated to all cells in an individual, yet that information can be expressed in different ways in each cell type. Both types of inheritance are necessary to facilitate the normal function of cells, tissues, and organs.

Glossary

Epigenetics Molecular factors and processes around DNA that regulate genome activity independent of DNA sequence, and which are mitotically or meiotically stable.

Epimutation An altered epigenetic mark at a specific chromosomal site, often in response to exposure to an environmental factor.

Transgenerational epigenetic inheritance Germline (sperm or egg) transmission of epigenetic information between generations in the absence of any continued direct exposures or genetic manipulations.

It is self-evident that the environment has a strong effect on the biology of an organism. Changes in the environment or exposure to environmental toxicants can result in changes in gene expression and development of pathologies or phenotypic variation. Epigenetic factors are the molecular mechanisms an organism uses to respond to environmental changes with changes in gene expression. Although more traditional definitions exist (Skinner, 2011; Skinner et al., 2010), a modern mechanistic definition of epigenetics is:

Molecular factors/processes around the DNA that regulate genome activity independent of DNA sequence, and that are mitotically stable.

The term epigenetics was coined by Dr. Conrad Waddington, University of Edinburgh, in the 1940s to describe gene-environment observations that could not be explained with classic genetics (Waddington, 1942). In the 1970s DNA methylation was the first epigenetic molecular mark to be characterized. With DNA methylation a small (methyl) chemical group is attached to DNA, primarily at the cytosine base in animals (Holliday and Pugh, 1975; Singer et al., 1979). In the 1990s the histone proteins that DNA is wrapped around were also found to be chemically modified to alter gene expression (Loidl, 1994; Davie, 1998). In the 2000's non-coding RNA molecules were identified that can act as epigenetic factors (Kornfeld and Bruning, 2014). The coiling, looping and general structure of DNA, termed chromatin structure, is also an epigenetic factor (Yaniv, 2014). Additional DNA cytosine modifications have also been described (Liu et al., 2016). More recently RNA methylation has been shown to alter gene expression and cellular function. The currently known epigenetic molecular processes are DNA cytosine modifications, histone modifications, functional non-coding RNA, RNA methylation and chromatin structure. All these epigenetic processes are important and have distinct roles in the regulation of how genes are expressed in the genome, independent of DNA sequence. New epigenetic marks and processes will also likely be identified in the future.

The vast majority of environmental factors and toxicants do not have the ability to alter DNA sequence or promote genetic mutations (McCarrey, 2012). In contrast, the environment can dramatically influence epigenetic processes to alter gene expression and development. Therefore, epigenetics provides a molecular mechanism for the environment to directly alter the biology of an organism (Jirtle and Skinner, 2007). An altered epigenetic mark at a specific chromosomal site in response to an environmental factor is termed an "Epimutation" (Skinner et al., 2010). Therefore, DNA sequence changes are genetic mutations, while environmentally altered epigenetic sites that influence genome activity are epimutations.

Epigenetic changes can be inherited across generations, and can result in changes in gene expression and phenotype in subsequent generations, even after exposure to the environmental changes or factors has ceased. "Epigenetic Transgenerational Inheritance" is defined as (Skinner et al., 2010; Skinner, 2014):

Germline (sperm or egg) transmission of epigenetic information between generations in the absence of any continued direct exposures or genetic manipulations.

An early study on the toxicant actions of the agricultural fungicide vinclozolin illustrates the epigenetic transgenerational inheritance phenomenon (Anway et al., 2005). F0 generation pregnant rats were exposed to vinclozolin at the time of fetal sex determination and the direct effects on the F1 generation adults were identified. The F1 generation adult males developed a testis abnormality. When the F1 generation offspring was bred to generate the F2 generation (grand-offspring) the F2 generation adult males were found to have the same testis defects as the F1 generation. When the animals were bred to the transgenerational F3 and F4 generations the adult testis defect continued in over 90% of all male progeny (Anway et al., 2005). As the animals aged, both males and females developed disease in a variety of organs (Anway et al., 2006). The frequency of the abnormality did not decline at each generation, but stayed high suggesting a non-Mendelian phenomenon not following classic genetic processes.

Table 1 Environmentally induced epigenetic transgenerational inheritance

<i>Environmental toxicants</i>	
Vinclozolin (agricultural fungicide)	Permethrin and DEET (insect repellant)
Methoxychlor (agricultural pesticide)	DDT (pesticide)
Dioxin/TCDD (industrial contaminant)	Tributyltin (industrial toxicant and biocide)
Plastic compounds (BPA and phthalates)	Hydrocarbons (jet fuel)
<i>Other types exposures</i>	
Nutrition (high fat or caloric restriction)	Smoking and alcohol
Temperature and drought (plant health and flowering)	Stress (behavioral)

When the male vinclozolin lineage animal was outcrossed to a wildtype female the transgenerational phenotype was maintained at the same frequency, but a reverse outcross of a vinclozolin lineage female to a wildtype male resulted in loss of the phenotype (Anway et al., 2005). Therefore, a transgenerational phenomenon was observed that was transmitted through the male germline (sperm). Later experiments with other toxicant exposures (Table 1) have shown transmission through the female germline predominantly (Manikkam et al., 2014), such that the transgenerational phenotype is transmitted in a parent of origin allelic manner, similar to imprinted genes.

To understand transgenerational phenomena it is essential to distinguish between direct exposure effects versus germline (sperm or egg) mediated transgenerational events. When a gestating female is exposed, that F0 generation female, the F1 generation fetus and the germ cells (sperm or eggs) that are inside the fetus and that will produce the F2 generation, are also directly exposed, Fig. 1. Therefore any effects seen in the F0, F1 and F2 generations may be due to direct exposure toxicity as well as to environmentally induced epigenetic changes. Examination of the F3 generation (great grand-offspring) is minimally needed to assess transgenerational phenomenon, since direct exposure effects are not involved (Skinner, 2008), Fig. 1. In contrast, in the event an adult male or non-pregnant female is exposed to an environmental factor, then the F0 generation adult and the germ cells that will

Fig. 1 Environmental factor exposure example showing an F0 generation pregnant animal exposed to a toxicant, and illustrating that the multigenerational F1 and F2 generations were also directly exposed, while the transgenerational F3 generation had no direct exposure. Adapted from Skinner, M. K. 2008. What is an epigenetic transgenerational phenotype? F3 or F2. *Reproductive Toxicology*, 25, 2–6.

generate the F1 generation are directly exposed, and examination of the non-exposed F2 generation (grand-offspring) is required to demonstrate a transgenerational phenomenon. When multiple generations are directly exposed, this is referred to as a multigenerational exposure, which has been shown to have effects with a variety of exposures (Skinner et al., 2010). The ability to transmit information from one generation to the next requires the sperm or egg so transgenerational events are germ cell mediated (Fig. 1).

Consideration of environmentally induced epigenetic transgenerational inheritance is anticipated to have a significant role in all areas of biology. Knowledge of environmental epigenetics and epigenetic inheritance will help to better understand how environmental factors and toxicant exposures can influence our health and disease across generations. In addition, epigenetic transgenerational inheritance will have a critical role in evolution (Skinner, 2015).

Glossary

Epigenetics Molecular factors and processes around DNA that regulate genome activity independent of DNA sequence, and which are mitotically stable.

Transgenerational epigenetic inheritance Germline (sperm or egg) transmission of epigenetic information between generations in the absence of any continued direct exposures or genetic manipulations.

Epigenetic processes are some of the main ways that organisms respond to their environment with changes in gene expression. In addition, it is primarily by epigenetic mechanisms that one cell type is able to differentiate and change to develop into another cell type. Epigenetics is defined as: “Molecular factors/processes around the DNA that regulate genome activity independent of DNA sequence, and that are mitotically stable” (Skinner, 2011). There are a variety of epigenetic factors that act around the DNA in a cell to regulate gene expression. In the 1970s DNA methylation was the first epigenetic molecular mark to be characterized. With DNA methylation a small (methyl) chemical group is attached to DNA, primarily at the cytosine base in animals (Holliday and Pugh, 1975; Singer et al., 1979) to produce 5-methylcytosine (5mC). Other chemical modifications of cytosine bases in DNA have since been described. The TET family of enzymes can successively oxidize 5mC to 5-hydroxymethylcytosine (5hmC), 5-formylcytosine (5fC) and 5-carboxylcytosine (5caC) (Kriaucionis and Tahiliani, 2014). In broad terms, the presence of 5mC often represses DNA transcription, while 5hmC is permissive to transcription (An et al., 2017; Mellen et al., 2017). The functions of the other epigenetic modifications to cytosine are under investigation. N(6)-methyladenine is an epigenetic modification to the adenine base of DNA that was once thought to only be present in prokaryotic organisms, but has now been described in mammalian embryonic stem cells (Wu et al., 2016).

The histone proteins that DNA is wrapped around create the nucleosome and can be chemically modified to alter gene expression. There are many different histone post-translational modifications including lysine acetylation, lysine and arginine methylation, arginine citrullination, lysine ubiquitination, lysine sumoylation, ADP-ribosylation, proline isomerization, and serine/threonine/tyrosine phosphorylation (Rothbart and Strahl, 2014). These modifications can change chromatin structure or recruit transcriptional cofactors to DNA in order to regulate gene expression.

Non-coding RNA molecules can act as epigenetic factors (Kornfeld and Bruning, 2014). These are small RNA molecules that do not code for a protein, but rather function as RNA to regulate gene expression. The non-coding RNA molecules that act as epigenetic factors are not DNA sequence dependent, so the majority do not depend on having a nucleotide sequence that is complementary to a specific DNA or RNA region in order to function. Long non-coding RNAs (lncRNAs) (Wei et al., 2017) and transfer RNA-derived small RNAs (tsRNAs) (Chen et al., 2016a) are examples of RNA classes that are present in sperm and can act as epigenetic factors that affect subsequent generations (Chen et al., 2016b).

The coiling, looping and general structure of DNA, termed chromatin structure, is also an epigenetic factor (Yaniv, 2014). The three-dimensional structure of DNA can make certain regions of the genome accessible to transcription machinery, or bring enhancer regions near to gene promoters, and so affect gene expression. Therefore, epigenetic molecular processes include DNA methylation, histone modifications, non-coding RNAs, RNA methylation and chromatin structure.

Two well-studied examples of epigenetic processes are X-chromosome inactivation and imprinted genes (Lee and Bartolomei, 2013; Henckel et al., 2012). Female mammals have two X-chromosomes and one must be inactivated for normal biological function. This has been shown to involve DNA methylation, histone modifications and long non-coding RNA (Sado and Ferguson-Smith, 2005). Imprinted genes are a small set of genes that are expressed from either the mother's (maternal) or father's (paternal) contributed DNA (allele), but not both. Imprinting involves DNA methylation, histone modifications, chromatin structure and non-coding RNA to control this parent of origin gene expression (Massah et al., 2015). These examples show how epigenetics and genetics cooperate to control genome activity and normal biology.

Altered epigenetic marks at specific DNA sites in response to exposure to an environmental factor are termed “epimutations” (Skinner et al., 2010). Thus, DNA sequence changes are genetic mutations, while environmentally altered epigenetic sites that influence genome activity are epimutations.

Epigenetic information can be transmitted to subsequent generations, and can change gene expression and an organism's phenotype even in transgenerational generations that were themselves never exposed to an inducing factor like an environmental toxicant. The ability to transmit epigenetic information from one generation to the next requires that epigenetic factors be present in sperm or eggs. If the sperm or egg cells are transmitting epigenetic information transgenerationally then epimutations should be detectable in these germ cells. Analysis of the F3 generation (great-grand-offspring) sperm from a line of rats in which the F0 generation pregnant females were treated with the environmental toxicant vinclozolin were found to have sperm epimutations consisting of altered DNA methylation, compared to controls (Guerrero-Bosagna et al., 2010). Interestingly, a variety of different environmental toxicants,

Fig. 1 Role of germline in epigenetic transgenerational inheritance. Summary of environmentally induced epigenetic reprogramming of primordial germ cells that leads to the germline transmission of epimutations, resulting in all somatic cells having altered gene expression. This can result in changes in phenotype or increased disease susceptibility in the F1, F2 or transgenerational F3 generation. Modified from Skinner, M. K., Manikkam, M. & Guerrero-Bosagna, C. 2010. Epigenetic transgenerational actions of environmental factors in disease etiology. *Trends in Endocrinology and Metabolism*, 21, 214–22.

each shown to promote transgenerational disease, were each found to promote a unique signature or pattern of epimutations in their F3 generation sperm (Manikkam et al., 2012).

The example of the processes involved in environmentally induced epigenetic transgenerational inheritance is presented in Fig. 1. The exposure of an F0 generation gestating female to an environmental factor at the critical window of gonadal (testis or ovary) sex determination in the F1 generation fetus modifies the epigenetic programming of the germ cell that the F1 generation adult animal will transmit to the F2 generation. All cell types and tissues derived from cells carrying epimutations will have an altered epigenome and potentially have altered gene expression. For example, isolated transgenerational cells such as Sertoli cells from the testis or granulosa cells from the ovary have been shown to have a transgenerational alteration in gene expression and epigenetics (Guerrero-Bosagna et al., 2013; Nilsson et al., 2012). Tissues sensitive to an altered gene expression profile will have a different phenotype, and may develop disease or abnormalities as the individual ages. For example, the testis and ovary develop pathologies that are associated with the somatic cell epigenetic alterations (Guerrero-Bosagna et al., 2013; Nilsson et al., 2012). An adult F2 generation individual will then transmit germ cell epimutations to the transgenerational F3 generation, and the same mechanism and process can occur in all subsequent generations, Fig. 1.

Environmental exposures can promote non-genetic inheritance through epigenetic transgenerational inheritance mechanisms to promote disease and altered phenotypes in subsequent generations. The potential role of this mechanism in our understanding of disease etiology needs to be considered. For example, environmental exposures in past generations could contribute to the incidence of abnormalities and disease in the current human population. Epigenetic transgenerational inheritance will also have critical roles in other biological processes such as evolutionary biology (Skinner, 2015).

Glossary

Epigenetics Molecular factors and processes around DNA that regulate genome activity independent of DNA sequence, and which are mitotically stable.

Transgenerational epigenetic inheritance Germline (sperm or egg) transmission of epigenetic information between generations in the absence of any continued direct exposures or genetic manipulations.

Introduction

Epigenetics is the molecular factors and processes around the DNA that regulate genome activity independent of DNA sequence, and that are mitotically stable (Skinner, 2011). Epigenetic mechanisms are crucial for normal biology and are some of the primary drivers of cell differentiation that produce all the different cell and tissue types in an organism (Klironomos et al., 2013; Skinner et al., 2014b). In addition, epigenetic activity is a normal mechanism by which organisms respond to alterations in the environment by changing gene expression (Aguilera et al., 2010; Gomes and Pelosi, 2013). Epigenetic processes include DNA methylation, modifications to histone proteins, expression of non-coding RNA, and changes to chromatin structure.

It is possible for epigenetic changes and epigenetic responses to environmental factors to be inherited across generations (Anway et al., 2005; Song et al., 2013). Ancestral exposure to environmental factors or toxicants has been shown to promote changes in gene expression and disease frequency (Skinner, 2014). Transgenerational epigenetic inheritance can occur if epigenetic alterations and changes in an organism's phenotype are inherited through the germ line in generations that were themselves never exposed to an inducing factor like an environmental toxicant. Transgenerational epigenetic inheritance requires that epigenetic information or epigenetic changes are present in germ cells (i.e., sperm or eggs), as it is through germ cells that inheritance occurs. This chapter reviews the diversity of organisms and species for which epigenetic transgenerational inheritance has been shown to occur (Table 1).

Overview

Epigenetic transgenerational inheritance phenomena have been shown in many plant species. For example, cold temperature and drought can promote epigenetic transgenerational inheritance of flowering and growth characteristics. These processes involve heritable changes in DNA methylation (Song et al., 2013; Quadrana and Colot, 2016).

In the nematode worm *C. elegans* epigenetic transgenerational inheritance has been shown to occur (Vaiserman et al., 2017). For example, increased longevity that is associated with the histone modification H3K4me3 methylation can be transgenerationally inherited for up to three generations (Greer et al., 2011). Similarly, specific changes in gene expression after an ancestor is exposed to heat shock can be epigenetically inherited for as many as 14 generations (Klosin et al., 2017).

The model insect species *Drosophila melanogaster* has been used in a number of studies investigating epigenetic transgenerational inheritance (Grentzinger et al., 2012). Interestingly, one of the first experiments to establish the potential for epigenetic transgenerational inheritance was performed by Conrad Waddington, who coined the term "epigenetic" (Waddington, 1942, 1953). In these studies it was found that a heat shock induced wing structure changes that persisted for more than seven generations. In more recent examples, it has been found that a high-sugar maternal fly diet can alter the larval body composition for the next two generations (Buescher et al., 2013). Manipulations of the protein levels in the diet of fruit flies can affect longevity and reproduction for three subsequent generations, and is associated with histone modifications (Xia and de Belle, 2016; Xia et al., 2016).

Other arthropod species have also demonstrated epigenetic transgenerational inheritance. The brine shrimp *Artemia* is a genus of crustacean species that have shown the inheritance of an acquired immune resistance (Norouzitallab et al., 2014). In these studies, *Artemia* were exposed to a bacterial pathogen that did not kill them, and to which they developed resistance. Three generations later the *Artemia* were still more resistant to that bacteria. This was associated with changes in DNA methylation and histone acetylation. In *Daphnia magna*, another crustacean species, it was shown that exposure to the toxicant 5-azacytidine resulted in decreased body length and reduced levels of DNA methylation in non-exposed subsequent generations (Vandegheuchte et al., 2010).

Several species of fish have shown epigenetic transgenerational inheritance. Zebrafish exposed to the environmental toxicants benzo(a)pyrene (Knecht et al., 2017), methylmercury (Carvan et al., 2017) or dioxin (Baker et al., 2014) have shown in their grand-offspring behavioral changes, visual defects, increased body mass, skeletal abnormalities and/or decreased fertility, some of which are associated with changes in DNA methylation. Medaka exposed to the endocrine disruptors bisphenol A (BPA) or ethinylestradiol produced grand-offspring and great-grand-offspring with reduced fertility (Bhandari et al., 2015). The pipefish

Table 1 Epigenetic transgenerational inheritance across species

Species	Exposure	Transgenerational phenotype	Generation	References
Plant species	Cold, drought	Change in flowering, growth	F2 +	Quadrana and Colot (2016) and Song et al. (2013)

Mouse	Cage enrichment, vinclozolin, diabetes	Behavior change, increased disease rate, infertility	F2, F3	Yeshurun et al. (2017), Guerrero-Bosagna et al. (2012), and Pavlinkova et al. (2017)
Guinea pig	Ethanol	Reduced fertility	F4	Stockard and Papanicolaou (1918)
Pig	Methyl donor diet	Decreased backfat	F2	Braunschweig et al. (2012)
Human	Calorie restriction	Increased diabetes, mortality	F2	Veenendaal et al. (2013) and Bygren et al. (2001)

Syngnathus typhle has shown transgenerational inheritance of increased expression of immune response genes after grand-parental exposure to heat-killed bacteria, also associated with changes in DNA methylation or histone modifications (Beemelmanns and Roth, 2017).

Some bird species have shown evidence of epigenetic transgenerational inheritance. In a study with quail, eggs were injected with the environmental estrogen genistein (Leroux et al., 2017). In the great-grand offspring the age at which the first egg was laid was significantly greater in genistein-lineage quail compared to the control lineage. Ancestral diet has been shown have a transgenerational effect in ducks (Brun et al., 2015). Ducks fed a methionine-deficient diet produced grand-offspring with altered weight gain and changes in metabolic parameters.

In mammals most studies of epigenetic transgenerational inheritance have occurred in rodents (Skinner et al., 2011). Examples of epigenetic transgenerational inheritance in rats include increased rates of reproductive abnormalities in great-grand offspring after exposure of pregnant rats to the environmental toxicant vinclozolin (Anway et al., 2005) and transgenerational inheritance of altered behaviors (Gillette et al., 2014), both associated with altered DNA methylation. Alterations in longevity and body weight have been seen in grand-offspring after non-pregnant grandmothers were fed a calorie restricted diet (Araminaite et al., 2014).

In mice, males who experience an enriched living environment had grand-offspring with changes in behavior and neuro-endocrine parameters (Yeshurun et al., 2017). Other examples of epigenetic transgenerational inheritance in mice include transgenerational increases in adult onset disease and changes in DNA methylation after ancestral exposure to vinclozolin (Guerrero-Bosagna et al., 2012), and male diabetes resulting in increased rates of infertility in grand-offspring (Pavlinkova et al., 2017).

Interestingly, a study in Guinea pigs from 1918 demonstrated transgenerational inheritance of decreased fertility and increased mortality for four generations after ancestral exposure to ethanol vapor, although this was not attributed to epigenetic inheritance at the time (Stockard and Papanicolaou, 1918).

The domestic pig is another mammal that has shown evidence of epigenetic transgenerational inheritance. Male pigs fed a diet high in methylating micronutrients had grand-offspring with a lower level of backfat (Braunschweig et al., 2012). This change in carcass fat percentage was accompanied by differences in DNA methylation levels of selected genes in liver and muscle.

Evidence of epigenetic transgenerational inheritance in humans comes from retrospective studies (Veenendaal et al., 2013). For example, the Overkalix region of northern Sweden experienced periods of famine in the early 1900s, and the descendants of those people exposed to famine conditions as children 9–12 years of age were investigated (Bygren et al., 2001). It was found that men whose grandfathers were exposed to famine had an increased risk of mortality due to diabetes, and similarly women whose grandmothers were exposed had increased risk.

Conclusions

Epigenetic transgenerational inheritance has been demonstrated to occur across a wide variety of eukaryotic phyla and species, including plants, nematode worms, insects, crustaceans, quail, ducks, rats, mice, Guinea pigs, domestic pigs, and humans. This suggests that epigenetic transgenerational inheritance is a broadly conserved phenomenon, and likely has some adaptive value for each species.

The question that then arises is why can environmental insults sometimes result in transgenerational inheritance of increased disease susceptibility, which is a maladaptive response? One possible answer may be explained by the predictive adaptive response hypothesis (Skinner et al., 2014a; Bateson et al., 2014). In this hypothesis an environmental stressor like famine may epigenetically promote an adaptive (thrifty) phenotype in progeny. If the current environment of those progeny has more than adequate nutrients, diseases like diabetes and obesity are promoted. Another possibility is that an environmental insult, such as exposure to a toxicant, may interfere with the normal molecular epigenetic machinery and result in stochastic and/or directed epigenetic changes that could be considered epimutations. If these epimutations occur in germ cells, then that can lead to transgenerational inheritance of a wider range of phenotypes in the progeny. Some of those phenotypes may be poorly adapted and develop disease. This would explain an increase in disease susceptibility in organisms whose ancestors were exposed to environmental insults. However, the increased phenotypic variation may also result in some individuals who are better adapted to an altered environment, facilitating natural selection (Skinner, 2015).

Glossary

Embryogenesis The process by which the **embryo** forms and develops inside the mother's womb.

Endocrine disruptors Man-made or natural chemicals that can interfere with the endocrine systems and disrupt the normal functions. These disruptions can cause cancerous tumors, birth defects, and other reproductive, and developmental disorders.

Environmental contaminants Substances when accidentally or deliberately introduced into the environment, may have the potential to harm people, wildlife, and plants.

Gametogenesis The development and production of the male and female germ cells required to form a new individual.

Oogenesis The differentiation of the ovum into a cell competent to further development when fertilized. It is developed from the primary oocyte by maturation.

Spermatogenesis The process in which an animal produces spermatozoa from spermatogonial stem cells by way of mitosis and meiosis.

Environmental Impact on Reproduction

Environment has great impact on human reproduction especially during gametogenesis and embryogenesis. Gametogenesis starts from the formation of gametes in the testes or ovaries, followed by embryogenesis, the development of embryo inside the mother's womb. Environmental factors such as life style and occupational exposures to contaminants can cause adverse effects on gametogenesis and embryogenesis. The interaction between early stage of development and the environment has extensively been studied and risks posed by changing lifestyle and the environmental contaminants have been proven to significantly impact our health, either directly by exposing people during early stage of development, or indirectly by disrupting quality of spermatocytes in male or oocytes in female. Changes in the environment due to industrialization have great impact on decreasing sperm quality, which is closely associated to low fertility in females, possibly due to combination of low fertilization rates, and increase embryonic mortality. For instance, observation of adverse trends in male reproductive health together with declining sperm count in Denmark and other countries led to the hypothesis that environmental contaminants having endocrine disrupting properties are harmful to reproductive health. In support of the above studies, a cohort analysis of nearly 45,000 pairs of twins from Sweden, Denmark, and Finland concluded that the environment rather than genetics played a critical role in sporadic cancers of the prostate, breast, and female reproductive system. The endocrine system controls the release of hormones which keeps the body functions normal. However, some environmental or man-made contaminants can impede the endocrine functions by mimicking or blocking hormone response that can disrupt the normal processes of development and reproduction, leading to adverse conditions. A large number of chemicals, mainly pesticides, and industrial wastes possessing estrogenic and/or antiandrogenic properties, are implicated as environmental contaminants. Prolonged exposure to small amounts of environmental contaminants leads to accumulation of considerable burden in animal and human tissues. The US Environmental Protection Agency (EPA) has defined endocrine-disrupting compound as "an exogenous agent that interferes with synthesis, secretion, transport, metabolism, binding action or elimination of natural blood-borne hormones that are present in the body and are responsible for homeostasis, reproduction, and developmental process."

Endocrine disruptors are highly heterogeneous molecules, some of them are synthetic chemicals used as industrial solvents/lubricants and their byproducts such as plastics, plasticizers, pesticides, fungicides, and pharmaceutical agents. Susceptibility of individuals to environmental contaminants depends on genetic polymorphisms because each person has unique exposure to a variety of known as well as unknown endocrine disruptors. Individual differences in the metabolism and body composition create considerable variability in the half-life, persistence, degradation in body fluids, and tissues. Initially estrogenic endocrine disruptors received much attention, but soon after antiandrogenic and thyroid hormone disrupting compounds have come into focus due to their adverse effects on reproduction. The mechanisms of action of endocrine-disrupting chemicals were not well understood and were originally proposed to exert their effect primarily through nuclear hormone receptor but recent studies show that the mechanisms are much broader than were originally documented.

Gametogenesis and Embryogenesis of Reproductive Organs

The male and female reproductive systems are under the control of hypothalamic-pituitary-gonadal axis. They interact to fulfill the main roles, in case of female, synthesizing sex hormones, development of female gametes, transport of gametes to a site where sperm can fertilize them, and provide a favorable environment for the development and delivery of the fetus. In the early stage of embryonic development, the two sexes are indistinguishable and a genetic program involving *SRY* gene in the Y chromosome determines the gonadal sex. In the presence of Y chromosome the *SRY* gene directs the gonad to become testis whereas in the absence develops into ovary. Sertoli cells in the testis produce anti-Müllerian hormone (AMH) that induces involution of the paramesonephric duct, also called Müllerian duct. In the absence of AMH it develops into oviducts, uterus and the upper part of vagina. Leydig cells produce testosterone that stimulates fetal mesonephric ducts, also called Wolffian ducts, to develop into epididymides, ejaculatory duct and seminal vesicles. Therefore, hormones play very important role in sex differentiation during early embryonic stage; any adverse effect by environmental contaminants possessing hormonal properties directly interfere the normal development of male or female reproduction.

The testis and ovary act as endocrine glands as well as reproductive organs. They play important role in the production of androgen and spermatozoa in the case of male, and estrogen and egg in the case of female. Spermatogenesis is the formation of the male gamete or spermatozoa and is dependent on the integrity of the seminiferous tubules, Sertoli cells, and endocrine regulation. In response to LH, Leydig cells produce testosterone, which along with FSH binds to Sertoli cell receptors to regulate spermatogenesis. The proper functioning of each organ in the reproductive system is essential to the operation of these complex processes. In animals and humans, there is a potential lag between exposure to factors from change in life-style or environmental contaminants, and manifestation of reproductive disorders because infertility cannot be assessed until the exposed individual attains reproductive age. Adverse effects on male or female reproduction by endocrine disruptors include feminization, demasculinization, reduced fertility, hatchability, viability of the offspring, impaired hormone secretion or activity, and altered sexual behavior.

Lifestyle and Gametogenesis

Lifestyle and morbidity associated with lifestyle due to habitual use of alcohol, tobacco, social or entertainment drugs, improper diet, obesity, and lack of exercise often negatively correlate with reproductive potential. Obesity not only affect the individual reproductive gametes but also impairs metabolic and reproductive health of the offspring suggesting that paternal health cues are transmitted to the next generation via the sperm. Obesity reduces inhibin B, which downregulates FSH biosynthesis and secretion, and thereby decreases spermatogenesis. High fat diet and obesity decrease the number of Sertoli cells and alter testosterone and estradiol ratio. Dietary soy which contains phytoestrogen has deleterious effects on male fertility by mimicking the action of estrogen. In case of female, obesity is associated with the alteration in ooplasm of egg that affects fertilization and implantation. Alcohol consumption can severely affect male fertility by decreasing sperm production and Sertoli cell numbers. Habitual smoking affects all stages of sperm production, sperm count, sperm concentration, sperm morphology, libido, and sometimes causes erectile dysfunction. Nicotine is one the components of tobacco, which causes damage to the DNA of spermatozoa, Leydig cell apoptosis, and hampers androgen production. Nicotine also induces Sertoli cell vacuolization, decreases the number of differential germ cell population and degenerative changes in seminiferous tubules. In case of female, smoking drastically impairs the functions of granulosa cells, hampers oocyte meiosis, depletes primordial follicles, decreases steroidogenesis, and increases the chances of aneuploidy.

Environmental Contaminants and Gametogenesis

Gametogenesis occurs in the testes or ovaries, which have been reported as one of the major target organs for environmental contaminants. The effects of maternal or paternal exposure to adverse environmental factors can be projected to the future offspring, resulting in poor semen quality in the male offspring years later. Paternal exposure in conjunction with the exposure of the adult offspring can amplify the effects, while adverse environmental effects during adulthood are believed to be reversible, damage done before and up to puberty is considered to be irreparable. The environmental contaminants that affect the gametogenesis are grouped into several functional classes viz., estrogen analogues, dioxins, phthalates, polychlorinated biphenyls (PCBs), brominated flame-retardants, and heavy metals. A large number of environmental contaminants possessing endocrine disrupting properties are known to induce abnormalities during gametogenesis both in wildlife and humans. Exposure of female fetuses to androgen leads to the formation of masculine characters whereas exposure of male fetuses to antiandrogens results in under-masculinization or feminization. Furthermore, the development of male reproductive system is under the control of multiple hormones, male fetuses are more susceptible to endocrine disruption than females. A wide range of mechanisms of action are described for several environmental contaminants that affect gametogenesis including agonist of estrogen receptor (genistein, diethylstilbesterol, and bisphenol A), antagonist of androgen receptor (vinclozolin, linuron, procymidone, phthalates, and *p,p'*-DEE), and agonist of aryl hydrocarbon receptor (dioxins, polychlorinated biphenyls, polycyclic aromatic hydrocarbon, and polychlorinated dibenzofurans).

Environmental Contaminants and Spermatogenesis

Even though infertility is considered as an adult problem, several factors including lifestyle and environmental contaminants impact on fertility that have their origin much earlier in life, especially during fetal development. The number of sperm produced per day or daily sperm production is dependent on the numbers of Sertoli cells within the testes. The number of Sertoli cells in the testes depends on the proliferation of the cells during fetal and neonatal periods and any factor that alters FSH or estrogen levels during fetal, neonatal or peri-pubertal life directly affects the sperm count and testicular size in adulthood. The mean sperm counts in men have been shown to decline over the past 60 years and it has been hypothesized that environmental exposure to synthetic estrogenic chemicals and related endocrine active compounds may be responsible for a global decrease in sperm counts and decreased male reproductive capacity. Several organochlorine compounds such as DDT and its metabolites, hexachlorohexane, PCBs, polychlorinated dibenzofurans (PCDFs), and polychlorinated dibenzo-*p*-dioxins (PCDDs), due to their high lipophilicity preferentially bio-accumulate in the adipose tissue. The presence of DDT and its metabolites, HCH, PCBs, and PCDDs has been reported in the fluids of human reproductive tract, such as seminal fluid, cervical mucus, and follicular fluid.

Many chemicals affect spermatogenesis indirectly through their effect on Sertoli cells, [e.g., dibromochloropropane (DBCP), monoethylhexyl phthalate (MEHP)] rather than directly on the germ cells. Hexane, an environmental toxicant and its metabolite 2,5-hexanedione (2,5-HD), cause testicular atrophy, and 2,5-HD induces toxicity by altering Sertoli cell's microtubules by pyrole-dependent cross-linking. The cross-linking of cytoskeletal elements leads to altered protein trafficking in the Sertoli cell. Consequently there is altered paracrine support between Sertoli cells and germ cells. 2-Methoxyethanol (2-ME), an industrial solvent, is toxic to both the male and female reproductive system. In order to attain testicular toxicity 2-ME must be metabolized to 2-methoxyacetic acid (2-MAA) by alcohol and aldehyde dehydrogenases. All stages of spermatocyte development and some stages of spermatid development are affected by 2-ME, which more selectively destroy early- and late-stage pachytene primary spermatocytes. Sertoli cells also are the prime target for 2-ME. The mechanism of testicular toxicity of 2-ME induced germ cell death is by reducing the available purine bases thus causing decreased RNA synthesis in spermatocytes. Alternatively 2-ME induces germ cell death by interfering with signal transduction pathways within either Sertoli cells or germ cells, causing a disruption of cell-to-cell communication. When 2-ME is applied dermally it can cause a decline in epididymal sperm and testicular spermatid counts in rats. Cadmium, one of the heavy metals, is known to affect testicular function by altering the actin filaments of tight junctions of Sertoli cells. Blood levels of cadmium have been reported higher in men from industrialized areas and in current smokers. There is a strong correlation between cadmium levels and number of immotile spermatozoa, and teratozoospermia index.

Esters of *o*-phthalic acid or phthalate esters (PAE) are extensively used as plasticizers in medical devices and other consumer products. Due to their leaching property, they can enter into body from the environment. There are several different PAEs, diethyl hexyl phthalate (DEHP), and its metabolite monoethylhexyl phthalate (MEHP) cause early sloughing of spermatids and spermatocytes and severe vacuolization of Sertoli cell cytoplasm by altering the membrane. DEHP is not only a reproductive toxicant in the male (e.g., rodents) but it can significantly suppress estradiol production from preovulatory follicle granulosa cell. Tri-*o*-cresyl phosphate (TOCP), an industrial chemical used as a plasticizer in lacquers and varnishes, decreases epididymal sperm motility, and density. TOCP interferes with spermatogenic processes and sperm motility directly and not via an androgenic mechanism or decreased vitamin E. Vinclozolin, a fungicide that undergoes biotransformation and its metabolites can effectively act as antagonists to the androgen receptor and disrupts sexual differentiation of male rats. Yet another fungicide benomyl causes a reduction in the number of spermatocytes and produces multinucleated germ cells. Exposure to methoxychlor in rodents during gestation and lactation resulted in slightly smaller testes and epididymides and in lowered sperm counts in male offspring than in controls. Chlordane, another persistent organic pollutant, disturbs spermatogenesis and causes dose-related damage to the testes of mice. The organochlorine insecticides endosulfan and lindane alter the weights of the testis and accessory sex organs in male rats and methoxychlor decrease weights of the accessory sex organs, epididymal sperm counts, and motility by inducing oxidative stress.

PCBs make up a group of synthetic organic chemicals containing about 200 individual compounds, some PCBs bind to estrogen receptor (ER) and consequently exert their toxic effects through estrogenic activity. Some PCBs induce reproductive toxicity through the production of highly toxic free radicals. Rats exposed to mixtures of PCB demonstrated decreased antioxidant enzymes in the testes. The timing of exposure is an important factor that strongly influences the ultimate reproductive effect of exposure to endocrine disruptors. Dioxins act via aryl hydrocarbon receptor and interfere with nuclear receptor, causing genital malformations. The male reproductive system gets adversely affected by the exposure to TCDD which affects germ cells in the testes and reduces Leydig cell volume. Interestingly, prepubertal exposure of men to TCDD has an inverse association between serum concentration of TCDD and semen quality, whereas the men exposed at ages 10–17 years had a positive association with semen quality suggesting that timing of exposure have an impact upon the response to dioxin. The effects have been summarized in [Table 1](#).

Environmental Contaminants and Oogenesis

Environmental contaminants can adversely affect ovary, uterus, vagina, anterior pituitary, and/or steroid production that lead to reproductive disorders such as early puberty, infertility, abnormal cyclicity, premature ovarian failure/menopause, endometriosis, fibroids, and adverse pregnancy outcomes. One of the most common environmental contaminants bisphenol A (BPA) has been shown to increase the incidence of multiocyte follicles, altered fetal ovarian genes responsible for steroidogenesis and expression of microRNA that mediate gonadal differentiation and folliculogenesis in sheep. BPA also interfere with ovarian development by

Table 1 Effect of environmental contaminants on reproduction

S. no.	Environmental contaminants	Source	Effect on reproduction
1	Phthalate (di(<i>n</i>) butylphthalate, di(iso) butylphthalate, benzyl butyl phthalate, di(2-ethylhexyl)phthalate, diphenyl phthalate, diisononyl phthalate, dicyclohexyl phthalate	Plastics, cosmetics, cleaning products, medical devices, toys, and many other everyday products	Reduce anogenital distance, hypospadias and undescended testes in immature male, reduce male fertility, fetal toxicity, and malformation of male organs
2	Bisphenol A (BPA)	Adhesive and sealants, plastic bottles, food packaging, plastic toys, and sporting equipment	Germ cell apoptosis, reduction of sperm count, arrest spermatogenesis at meiosis, affects apical, basal ectoplasmic specialization, disrupt homologous recombination
3	Alkylphenol, nonylphenol, and octylphenol	Use to protect polymers and stabilizer in plastic food packaging industries	Reduce testosterone biosynthesis, reduce testicular size, male fertility, sperm count, and quality
4	Heavy metals (cadmium, lead, arsenic, mercury)	Anthropogenic activities, volcanic eruption, soil erosion, etc.	Increase testicular toxicity, low sperm count, motility, and density Fetal toxicity and malformation of male reproductive organs
5	Volatile organic compounds (toluene, benzene, xylene, etc.)	Paints, varnishes, waxes, cosmetics, degreasing, and hobby products	Testicular toxicity, low sperm count and motility, reduce male fertility, reduce anogenital distance, hypospadias
6	Triclosan	A broad spectrum antimicrobial agent, is widely used in personal care, household as well as health care products, including toothpastes, antibacterial soaps, shampoos, deodorants, cosmetics, kitchen utensils, toys, bedding, and clothes	Alters sperm morphology
7	Polychlorinated biphenyls and its congeners	A wide variety of applications including plasticizers, rubber, resins, carbonless copy paper, adhesives, paints, and inks	Disrupts Sertoli cell function, reduce sperm cell viability and count Alters ovarian steroidogenesis
8	Dioxins	By-products of industrial processes, smelting, chlorine bleaching of paper pulp and the manufacturing of some herbicides and pesticides, volcanic eruptions, and forest fires	Sex hormone disruptors, testicular dysfunctions, low sperm count, and sperm abnormalities. Germ cell apoptosis, decreased sperm count
9	Diesel fuel exhaust	Combustion of diesel fuel	Suppress testicular functions in rats. Prenatal exposure in animals leads to endocrine disruption after birth
10	DTT and its byproduct DDE, methoxychlor, lindane	Organochlorine pesticides	Reduce synthesis of testosterone, induce germ cell apoptosis, functional defects in sperm production and maturation

affecting the onset of meiosis in the fetal ovary in macaques, in CD-1 mice as well as in cultured human fetal oocytes. BPA affects the postnatal ovary by accelerating follicle transition, decreasing primordial and increasing primary follicle numbers in lambs and rats. Prenatal exposure to high doses of BPA increases cystic follicles, depleted corpora lutea, and reduced antral follicle numbers in rats. Bisphenol A exposure also adversely affects the postnatal ovary in vitro by inhibiting the growth of cultured mouse antral follicles, upregulating the expression of cell cycle regulators, and pro- and antiatretic factors thereby causing atresia. The effects of BPA on the ovary also depend on which other chemicals the ovary is exposed to. Interestingly, triclosan, an antibacterial and antifungal agent found in some consumer products, including toothpaste, soaps, detergents, toys, and surgical cleaning treatment interact with BPA thereby magnifying its presence in reproductive tissues in mice.

The increased expressions of liver X receptor α and sterol regulatory element binding protein members in the fetal human ovary are reported following DHEP exposure. Exposure to MEHP decreases the number of viable oocytes in fetal mouse ovaries by dysregulating the expression of Cu-Zn superoxide dismutase and mitochondrial respiratory chain protein such as Nd1. DEHP also impaired the assembly of primordial follicle in cultured newborn mouse ovaries. Methoxychlor increases the expression of a number of genes associated with cell death and primordial follicle activation in mice and lipid peroxidation in neonatal mouse ovaries. One of the major metabolites of methoxychlor, 1,1,1-trichloro-2,2-bis(4-hydroxyphenyl)ethane (HPTE), also inhibits follicular growth and induces atresia in antral follicles from adult mouse ovaries. In addition expression of genes regulating signal transduction, transport, cell cycle, adhesion, differentiation, motility growth, apoptosis, development, and metabolism also get altered.

Environmental Contaminants on Embryogenesis

Embryotoxicity is any morphological or functional alteration caused by chemical or physical agents that interferes with normal growth, homeostasis, development, and differentiation of fetus. Abnormal sex hormone exposure during critical periods of development has been postulated for pathological mechanism for embryotoxicity or teratogenicity. Several environmental chemicals possessing antiandrogenic properties, when administered in utero, affect the normal development of gonads and accessory sex organs in animal models. The endocrine disruptors having antiandrogenic properties are vinclozolin, procymidone, linuron, *p,p'*-DDE (1,1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethane) that act as androgen receptor antagonists. Endocrine disruptors possessing antiandrogenic properties such as phthalate esters reduce androgen synthesis. Most chemicals in commercial use have not been checked for possible developmental toxicity to fetus, infants, and children. Even after gestation damage may still occur and toxins can pass on to infants via breastfeeding. One of the historical examples of endocrine disruptors is diethylstilbestrol (DES) affecting female reproductive system. In utero exposure of females to DES is associated with the induction of vaginal carcinomas after puberty. DES exposure causes a characteristic T-shaped uterus, abnormal oviduct anatomy and function, and abnormal cervical anatomy. These effects are believed to occur through estrogen receptor α and abnormal regulation of *Hox* genes. DES administration to humans induces an increase in the incidence of cryptorchidism. Interestingly DES and other potent estrogens are capable of reducing androgen levels and expression of the androgen receptor proteins in rats. It raises a controversy that genital tract abnormalities got arisen from in utero exposure of potent estrogen were due to lowered androgen levels and/or action of estrogen.

In rats, organochlorine environmental contaminants such as kepone and methoxychlor cause masculinization of the exposed female rats, altering ovulation and exhibit male sexual behavior. In humans, estrogenic environmental contaminants can alter natural hormonal cycles and associate with breast cancer induction. Some environmental endocrine disruptors may function as promoters or inducers of carcinogenesis and DDT is one of such examples. Persistent environmental contaminants have been found to correlate with breast cancer incidence. Delayed testicular descent, reproductive dysfunction and sexual impotence have been reported in males occupationally exposed to synthetic estrogens. The widespread effects have been summarized in Table 2.

In rodents, TCDD is both embryotoxic and teratogenic. TCDD has avidity for the estrogen receptor and other receptors (e.g., Ah receptor). Intrauterine exposure to dioxins has been associated with subtle developmental changes in the fetus. In Wistar rats, exposure to TCDD during pregnancy delayed the development of the ovaries in the offspring and reduced the expression of

Table 2 Effect of environmental contaminants on embryogenesis

S. no.	Environmental toxicants	Source	Potential impact on embryogenesis
1	Mercury	Eating contaminated fish or shellfish, breathing vapors from spills or incinerated materials, skin contact with mercury at the workplace	Brain damage, mental retardation, poor coordination, blindness, seizures, nervous, and digestive system problems and renal damage
2	Lead	Paint containing lead, contaminated soil, water, and dust	Low birth weight and preterm birth and neurodevelopmental effects
3	Arsenic	Contaminated food, water, or air; occupational exposure, inhaling sawdust or smoke from arsenic-treated wood; exposure to high-levels of arsenic in soil	Congenital malformations
4	Sulfur dioxide and particulate matter	From polluted air	Increased risk of low birth weight
5	Polychlorinated biphenyls (PCBs)	Drinking water, breathing air or eating foods, or exposure to soil that are contaminated, via older electrical equipment or transformers	Lower birth weight, decreased motor skills, and depressed immune system
6	DDT	Exposure via agricultural work and accidental exposure	Increased risk of miscarriage, preterm birth and small for gestational age
7	Bisphenol-A (BPA)	Polycarbonate plastics, food, consumer products, and packaging	Birth defects and neurodevelopmental disorders
8	Pesticides	Food residues, agricultural settings, in-home use	Impaired cognitive, neurodevelopment and impaired fetal growth
9	Organic solvents	Industrial workplaces, numerous consumer products including plastics, dyes, detergents, food containers, carpeting and cleaning products, nail salons	Fetal loss and miscarriage
10	Phthalates	Plastics, cosmetics, cleaning products, medical devices, toys and many other everyday products	Reduced anogenital distance, hypospadias and undescended testes in immature male, reduced male fertility, fetal toxicity and malformation of male organs, birth defects, shortened gestational age and impaired neurodevelopment

steroidogenic acute regulatory (StAR) protein in fetal ovaries. 2-ME is also embryotoxic and teratogenic in several species. Several plant estrogens bind weakly to estrogen receptors α and β , and are able to induce weak estrogenic and antiestrogenic actions in mammalian tissues.

Environmental Effects on Developing Germ Cells

Introduction

In mammals, germ cell development starts during fetal life and ends up with mature gametes formation after puberty, along the whole reproductive lifespan of individuals. Although a common pattern can be recognized between male and female germ cell development, major differences are present, such as the prenatal occurrence of premeiotic and meiotic phases in oogenesis, the lengthy aging of immature, resting oocytes before ovulation, or the profound postmeiotic differentiation in spermatogenesis.

Gametogenesis is finely regulated at molecular, cellular, tissue, and organism levels; however, external physical and chemical agents can perturb the process, with adverse consequences on fertility and heredity. The environmental impact on germ cells largely depends upon the time of exposure and the developmental phases affected. Chronic exposures may be especially critical for resting oocytes, in which their effect can add up to progressive deterioration of structures and functions with time.

In addition to direct effects on germ cells themselves, environmental exposure may affect germ cells by targeting their supporting somatic niche or the endocrine hypothalamic–pituitary–gonadal axis. The picture is complex since, for instance, the somatic component of testicular and ovarian tissues creates also a structural and functional physiological barrier protecting the maturing gametes from interactions with exogenous molecules.

The ultimate effects on germ cells can be death, with a transient or irreversible decline in gamete production, or genetic and epigenetic alterations with potentially heritable consequences (**Fig. 1**). Additionally, germ cell tumors arising from totipotent primordial germ cells, and especially testicular tumors, have been associated to prenatal environmental exposures to endocrine disrupting chemicals (EDCs). EDCs include a variety of natural and man-made chemicals that may interfere with the body endocrine system, many of which have a long environmental persistence. These compounds are found in daily products, such as plastic food bottles, food cans, detergents, flame retardants, toys, cosmetics, and pesticides. EDCs are a chemical class of high concern for human reproduction, gametogenesis and fertility, which are all hormonally regulated processes.

Nowadays, the attention is moving from the characterization of specific physical and chemical agent hazards to a broader perspective, which aims at understanding the impact on germ cells of complex exposures, diet, and lifestyle habits included. Tobacco smoking is the most potent and widespread environmental toxicant able to induce the full spectrum of adverse effects on germ cells (**Beal et al., 2017**). In the near future, next generation sequencing capacities applied to pedigree genomic analyses will allow to identify the first unquestionable human germ cell mutagens among the most likely candidates, ionizing radiation, cancer chemotherapy, cigarette smoking, and air pollution (**Yauk et al., 2013**) (**Table 1**).

Also, the increasing knowledge about the molecular pathways underlying cell reaction to exogenous stimuli helps to assess the environmental impact on developing germ cells in terms of adverse outcome pathways (AOP), from molecular initiating events to ultimate health effects. This approach is being developed by the Organization for Economic Co-operation and Development (OECD) within its Chemical Testing Program.

Toxic Effects

In Western countries, between 1973 and 2011, the mean sperm count declined, on average, 1.4% per year with an overall decline of 52.4% (**Levine et al., 2017**). The etiology of this decrease is unclear. Sperm count has been plausibly associated with environmental and lifestyle influences, both prenatally and in adult life. In particular, endocrine disruption from chemical exposures (e.g., phthalates) or maternal smoking during critical windows of male reproductive development may play a role in prenatal life, while exposure to pesticides may play a role in adult life (**Fig. 1**). Adverse effects have been documented in many animal studies, in which treatment can be controlled and doses are generally higher than those encountered by humans. Results of human epidemiological surveys, where exposure occurs at low levels for long times, exposure levels are difficult to quantify, and many confounders may affect the study outcome, are less conclusive. Nevertheless, cumulative effects of various low-dose human exposures should not be overlooked.

The risk of environmentally induced cell death is particularly critical for oocytes, of which there is a nonrenewable, finite pool. A reduction of the oocyte number may lead to a shortened reproductive lifespan. Premature ovarian insufficiency (POI) is a medical diagnosis that affects about 1% of women before the age of 40. In more than 75% of cases the cause is undetermined. Environmental factors are suspected of contributing to the onset of POI (**Vabre et al., 2017**).

Studies in rodents have demonstrated that prenatal exposure to mild analgesics, such as paracetamol or indomethacin, may reduce ovarian follicle reserves (a warning sign of POI), possibly by inhibiting primordial germ cell proliferation or interfering with oocyte meiotic progression. Similar effects have been also shown for industrial chemicals like bisphenol A (BPA) and di(2-ethylhexyl) phthalate (DEHP). DEHP is the most widely used plasticizer as it produces a functional polymer with excellent characteristics for industrial and medical applications such as inertness, flexibility, transparency, and high resistance to heat and chemicals. However, DEHP is non-covalently bound to products and may therefore leach out after prolonged use, with potential human exposure through inhalation,

Fig. 1 A schematic representation of main stages of male and female germ cell development in mammals, with indication of prevalent mechanisms of environmental effects and their stage specificity. (A) Prenatal development. (B) Postpubertal development.

ingestion or dermal contact. The mechanisms underlying ovarian toxicity of these chemicals are still unclear and the extent to which their endocrine disrupting properties may contribute needs to be better elucidated. At a molecular level, markers of cell damage (oxidative stress and apoptotic cell death pathway) in follicular cells and oocytes have been reported. DEHP seems to affect oocytes also at an epigenetic level, with alterations of gene expression observed after *in vitro* or *in vivo* exposure of neonatal ovaries, due to DNA methylation changes of imprinted genes and genes critical for oogenesis.

In addition to direct effects on developing germ cells, DEHP and BPA *in utero* exposures have adverse effects on folliculogenesis, during both follicle assembly and recruitment phases. Since the quality and quantity of fertilizable oocytes are dependent on finely tuned paracrine signaling between the oocyte and the surrounding follicular cells, impairment of folliculogenesis will negatively

Table 1 Available evidence, in humans and animal models, for mutagenic potential of human relevant exposures to chemical or physical agents (all of them proven carcinogens in humans)

Agent	Humans		Animal models

affect germ cell development and female fertility. Although most of the evidence comes from studies with laboratory rodents and few epidemiological surveys are available so far, experimentally determined no-effect levels and human exposure concentrations suggest that safety margins are smaller than recommended, at least for the most highly exposed women (Johansson et al., 2017).

Data in rodents and humans support an effect of prenatal and adult smoking exposure on follicle stock depletion, likely caused by oxidative stress and apoptosis. Among the over 4000 chemical substances contained in cigarette smoke, polycyclic aromatic hydrocarbons are the most likely culprit, as they bind the aryl hydrocarbon receptor on the surface of granulosa cells and through this mechanism may activate pro-apoptotic genes and cause follicular atresia.

The germ cell killing effect of ionizing radiation is well ascertained in laboratory species. After the increasing success of anticancer therapies in children and adolescents, it is important to assess the risk of temporary or permanent sterility in radiotherapy cancer survivors. Fortunately, oocytes enclosed in primordial follicles and slowly cycling/quiescent spermatogonial stem cells, which represent the majority of target cells in women and the only cells with a regenerative potential in men, are relatively radioresistant with respect to the subsequent differentiation stages, growing follicles and committed proliferating spermatogonia; thus in many cases, fertility reduction is only a temporary effect. Notably, different variables influence the risk in women and men, which confirms the role of reproduction physiology in modulating environmental risks. For instance, in women, sterilizing doses decrease with age, as the remaining population of primordial follicles falls, while in men the length of the infertile period appears to increase with radiation dose, as expected on the basis of the survival curves for spermatogonial stem cells.

Genetic Effects

In the 1940s the scientific community started investigating how the genetic information transmitted by gametes could be affected by human exposure conditions. After the end of the Second World War, Hiroshima e Nagasaki populations were monitored for years to understand the transgenerational consequences of irradiation exposure of germ cells. Furthermore, the fast postwar industrial growth lead to the introduction in the environment of an exponential number of new chemical agents, to increasing pollution in several areas of the World, and to novel forms of occupational exposure conditions.

Cell and molecular events associated to the introduction of detrimental genetic changes affecting reproduction may be as complex and specific as the development of male and female gametes is differently organized (Fig. 1). At the same time, the molecular mechanisms dealing with DNA damage surveillance and repair are highly specific and reflect the different cell and chromosome organization during and between male and female gametogenesis process.

Paternal and maternal genomes within fertilized oocytes could be considered the last target of potential environmental effects on developing germ cells. However, this stage is short and is more interesting for mechanistic studies on DNA damage repair than for the assessment of environmental genetic risks. Thus, postfertilization exposures will not be addressed.

Experimental evidence for the action of mutagens in germ cells has been accumulated mainly using male rodents, while databases for female germ cells are poor, because of the intrinsic difficulty to perform analyses on this limited cell compartment. Data are sufficient to have a panel of model agents useful to predict, when necessary, the reasonable profile of action of unknown agents before testing them (Wyrobek et al., 2007) (Table 2).

Unlike the evidence about a toxic impact of environmental, occupational and lifestyle factors on human germ cells, very few studies have so far documented an increase of de-novo mutations due to human environmental exposure. Even for ionizing radiation no conclusive evidence has been obtained in the atomic bomb survivors' offspring and in other cohorts of radiation-exposed people, in spite of very well documented effects in mouse germ cells (Table 1). Beyond the obvious difficulty to set-up appropriate, parent-children, epidemiological or case-control studies, major limitations in genome-wide analytical methods have until now hampered the detection of small increases of genetic changes, at a few, not-necessarily coding, sequences. Genome sequencing, already successfully applied in a proof-of-principle study on the characterization and quantitation of germline mutations in the mouse induced by ethylnitrosourea (the most powerful chemical mutagen in male germ cells), holds promise to overcome these limits.

Table 2 Response of rodent germ cells to genotoxic agents, as assessed by exposing different cell stages and by applying postfertilization assays of clastogenesis, mutagenesis, aneuploidy (dominant lethal assay, heritable translocation assay, specific locus test, cytogenetic analysis of zygotes)

	Prevalent mechanism of action for the observed effects	Male germ cells						Female germ cells
Agent		Stem spermatogonia	Differentiating spermatogonia	Spermatocytes	Early spermatids	Late spermatids	Sperm	Oocytes
Therapeutic agents								
Bleomycin	Clastogenic	—	—	—	—	—	—	+++
Cisplatin	Clastogenic	—	—	—	—	—	—	+++
Colchicine	Aneugenic	n.a.	n.a.	n.a.	n.a.	n.a.	n.a.	+++

Griseofulvin	Aneugenic	n.a.	n.a.	n.a.	n.a.	n.a.	n.a.	+++

This table lists a selection of agents representative of different mechanisms of action. + = low response; ++ = mild response; +++ = high response; — = no response; n.a. = not assessed. Note that testing in female germ cells may not be as exhaustive as in male germ cells due to technical limitations.

Adapted from: Wyrobek, A. J., Mulvihill, J. J., Wassom, J. S., et al. (2007). Assessing human germ-cell mutagenesis in the Postgenome Era: A celebration of the legacy of William Lawson (Bill) Russell. *Environmental and Molecular Mutagenesis* 48, 71–95.

Genetic changes can occur both at the gene and at the chromosome level, depending on the mechanism of action and the exposure condition of each environmental factor. For example, gene mutations arise when exogenous compounds reaching the germ cells are able to produce chemical modifications of the DNA sequence. These changes (not all of them) may cause pathological gene variants, which can manifest their detrimental effects at different developmental stages of humans, from early fetal life to elderly. In general, gene mutations induced during gametogenesis do not impact on the gamete before fertilization. Thus these gene changes are not selected and are transmitted to the progeny of exposed individuals. According to *de novo* mutation detection by next generation sequencing, the spontaneous germline mutation rate is substantially lower than the somatic mutation rate and both rates seem to be higher in mice than in humans. The germ cell stage at the highest risk of environmentally induced gene mutations is the mitotically expanding spermatogonial compartment, because many mutagens act by introducing covalently bound adducts to the bases, which, if unrepaired before DNA replication, may induce mispairing and consequent base changes. Benzo(a)pyrene is an ubiquitous environmental pollutant and an ascertained human carcinogen that causes both somatic and male germline mutations. Notable differences in mutation spectra between somatic and germ cells have been reported pointing to male germ cell-specific DNA-repair mechanisms. Benzo(a)pyrene induces mutations in sperm not only after treatment of adult mice, but also after prenatal exposure of primordial germ cells. Also female germ cells may be target of benzo(a)pyrene genotoxicity, as shown by induction of DNA strand breaks in mouse oocytes and their surrounding cumulus cells.

Changes at the chromosome level may be due to a structural damage: several exogenous agents are capable to introduce break-ages into the double helix, or to produce lesions that indirectly cause the formation of such a break. Collectively, these chemicals are defined clastogens. Broken chromosomes are highly reactive and must be sealed, even though imperfectly, to avoid cell death; when more chromosomes are damaged at the same time (e.g., after exposure to high doses of physical or chemical agents) they can rearrange mutually. These events lead to gross genetic changes: loss of large stretches of DNA, duplications or spatial reorganization of the genetic information. Furthermore, at meiosis chromosomes must pair with their homologues. Unbalanced conditions due to structural aberrations may lead to defective chromosome segregation. On the whole, chromosome damage introduced during germ cell development may be associated, with different extents, to prefertilization or early postfertilization selection. Postmeiotic stages (spermatids and spermatozoa) are especially prone to the formation of chromosome breaks and rearrangements, as a consequence of both endogenous (e.g., oxidative DNA damage) and exogenous stressors (Table 2). A compound that has shown a marked clastogenic effect on postmeiotic male germ cells in the mouse is acrylamide. Acrylamide is used worldwide in various scientific and industrial processes, such as water treatment, in cosmetics, and for gel electrophoresis. It is also found in carbohydrate rich foods that have been cooked at high temperatures, and in tobacco smoke. Genotoxic effects on mouse germ cells have been demonstrated also after low-dose chronic treatment relevant to human exposure levels. It is the transformation of acrylamide to its highly DNA-reactive metabolite glycidamide by cytochrome P450 enzyme CYP2E1 that is mainly responsible for the reproductive toxicity of the

compound; CYP2E1 inhibition by chemicals such as resveratrol seems to ameliorate acrylamide effects on male germ cells. Further to genotoxic damage, acrylamide induces also cytotoxic effects in male and female mouse germ cells, with the latter showing impacts on developmental competence, cytoskeleton integrity, reactive oxygen species levels, apoptosis induction, epigenetic modifications and litter size. The potential exposure of large populations to acrylamide at low intake levels through food and smoking has raised concerns regarding its potential health effects, and ad-hoc investigations about possible adverse reproductive effects are certainly warranted.

A second class of well-known chromosome changes affects their number and not their integrity. In mammalian cells there are several structures involved in successful regulation of chromosome segregation, so that the number of genotoxins which can increase numerical changes is large and it includes those acting on tubulin dynamics, centrosome assembly, centromere function. Collectively, these genotoxins are defined aneugens. Again the differences between male and female gamete maturation processes add a further level of complexity; for example minimum effective doses in male and female gametogenesis can differ widely (Pacchierotti et al., 2007). It must be also considered that while gene mutations and/or chromosome structural changes can be virtually introduced along the whole gametogenesis (although stage specific response are described as a function of the mechanism of action of the mutagen and the damage repair capacity), numerical changes in maturing gametes can arise specifically during the two meiotic divisions. Colchicine, a well-known spindle poison, is the paradigm of aneugenic agents acting in male and female gametogenesis (Marchetti et al., 2016) (Table 2). Numerous data support that chromosome segregation checkpoint control in mammalian primary oocytes is more permissive than in primary spermatocytes, making female germ cells specifically sensitive to endogenous and exogenous sources of aneuploidy induction. Bisphenol A has been alleged to induce aneuploidy in mouse oocytes after prenatal or adult exposure, but the underlying adverse outcome pathway has not yet been elucidated (Pacchierotti and Eichenlaub-Ritter, 2011).

Down syndrome, which occurs in children with an extranumerary copy of chromosome 21, originates from missegregation of this chromosome pair of homologues. This condition has a typical maternal origin and it is further influenced by age. A well-described case of Down syndrome increase in an exposed human population has been reported after an event of water pollution caused by the insecticide trichlorfon in Hungary (Czeizel et al., 1993).

Epigenetic Effects

Epigenetic modifications consist in heritable changes in gene function without modification of DNA sequence. The epigenome is substantially plastic and responds to environmental changes with modifications that can be transmitted to daughter cells and across generations. This plasticity is functional for adaptation to a changing environment but it also makes epigenome potentially subjected to dysregulation and susceptible to the induction of epimutations.

Epigenetic modifications comprise three main mechanisms, DNA methylation, chromatin structure modifications and noncoding RNA (ncRNA). All these epigenetic mechanisms have important roles in the development of germ cells from primordial germ cell (PGC) differentiation and migration through meiotic process and maturation of functional gametes. Epigenetic dysregulation of these processes may have detrimental effect on gametogenesis and lead to reproductive dysfunction in adults. Moreover, epigenetic alterations can be retained along germ cell maturation and increasing evidence indicates that they can be transmitted across generations with potential effects on offspring health.

Experimental evidence on different animal models has shown that several toxicant exposures, occurring during prenatal or adult life can affect the germ cell epigenome. A sensitive window to the harmful effects of environmental toxicants is the differentiation of PGCs during prenatal life (Fig. 1). During this period, PGCs colonize the embryonic gonads and start their differentiation into a male or female pathway. A key epigenetic event associated to this process is the genome wide demethylation. At the same time, other epigenetic changes occur, such as modulation of histone modifications; furthermore, a correct balance in the expression of ncRNAs seems to be necessary for a correct PGC development.

The first demonstration that DNA methylation links maternal diet during pregnancy with offspring phenotype was obtained using a mouse model carrying a gene controlled by a methylation-sensitive regulatory region. In this model, treatment of pregnant mothers with BPA induced hypomethylation of the offspring gene with phenotype consequences. These effects could be counteracted by maternal dietary supplementation with methyl donors like folic acid or genistein. These observations raised the question whether prenatal exposures to chemicals that are not direct inhibitors or donors of DNA methylation/reaction can reprogram DNA methylation in PGCs and in the offspring in a physiologically relevant manner.

EDCs are the mostly investigated chemicals in relation to possible effects on PGCs that could be transmitted across multiple generations (Xin et al., 2015). Among them, vinclozolin, a fungicide with antiandrogenic properties, BPA and phthalates. Evidence of transgenerational effects has indeed been obtained, but the picture of the whole pathway, leading from initiating epigenetic changes in PGCs to ultimate reproductive impairment in the following generations, is still incomplete, with few studies, until now, walking the whole pathway step by step. Nevertheless, changes of DNA methylation status and miRNA expression in PGCs have been reported after exposure to vinclozolin. The window of exposure appears to be a critical factor in the manifestation of transgenerational phenotypes. Moreover, the extent to which the epigenetic changes drive the observed phenotypes across generations remains to be determined.

During adult male life, extensive epigenetic reprogramming for the production of functional sperm for fertilization is required during spermatogenesis. Emerging data suggest that the epigenome during this process is susceptible to environmentally induced

alterations. Exposure of adult male mice to particulate air pollution has been shown to increase global methylation of spermatogonia, which persists through spermatogenesis and remains elevated in spermatozoa. Different experimental studies have shown that exposure to toxicants such as acrylamide or EDCs can modify the gain and loss of methylation in sequences involved in genetic imprinting during spermatogenesis. In humans, various epidemiological studies have documented that chemical exposure, mainly cigarette smoking, are linked with alterations of sperm epigenome (Wu et al., 2015).

The mammalian sperm epigenome is suspected to be a mediator of transgenerational transmission of paternal environmental exposures. By now, an extensive literature exists reporting results of experimental studies aiming to relate paternal complex environmental exposure, lifestyle or nutrition conditions with sperm epigenome modifications and offspring health. For example, nutritional manipulation in fetal or adult rodent males, such as over/under-nutrition, prediabetic conditions or folate deficiency, induces differential methylation in sperm and metabolic disorders or birth defects in offspring (Schagdarsurengin and Steger, 2016).

Mature spermatozoa hold a series of ncRNAs that can mediate transgenerational effects. For example, mice subjected to early life traumatic stress exhibited, further to behavioral and metabolic changes, alterations in the abundance of several spermatozoal small ncRNAs, compared to an unstressed control. Progeny generated from injection of sperm RNA from the stressed fathers into embryos, exhibited similar behavior and metabolic patterns as the stressed fathers. This experimental evidence supports the concept that, at least in mice, sperm RNAs can transmit the response of an early life stress to the progeny. The sperm RNA content can be also modulated by dietary exposures (Chen et al., 2016). It appears that sperm may acquire ncRNAs either from their progenitor germ cells or from extracellular sources during epididymal maturation. Interestingly, sncRNAs were also found in human seminal exosomes.

During oogenesis, there are widespread transcriptional changes and de novo DNA methylation, allowing the oocyte to obtain fertilization and embryogenesis competency. A number of posttranslational histone modifications help direct de novo methylation events in the oocyte. All known classes of short ncRNAs are present in mouse oocytes; however, gene-knockout studies have provided evidence that only some of them are required for oocyte development. Several epigenetic changes have been shown in oocytes as a function of female aging, including lower genome-wide DNA methylation, specific histone acetylation and methylation changes, follicular fluid microRNA changes.

In spite of the increasing knowledge about the epigenetic determinants of oocyte quality and of the evidence about maternal effects on epigenetic transgenerational inheritance in human cohorts, so far only a few sparse studies addressed directly the question of possible chemical effects on mammalian oocyte epigenetic setting. An obvious technical difficulty resides in the small number of oocytes collectable from any experimental group. The focus has been mainly on the methylation status of imprinted genes, with specific changes observed, for instance, after prenatal exposure of mice to DEHP, or neonatal exposure of mice to BPA. Imprinted gene methylation changes in mouse oocytes were also associated to a diabetic condition or to a high-fat diet adult exposure. In addition, small but significant histone methylation changes have been reported after exposure of oocytes to BPA or acrylamide. Conversely, the possible role of oocyte-borne sncRNAs in environmentally induced transgenerational phenomena is so far unknown and warrants future investigations.

An open question remains about the relevance of experimental studies for human exposure, especially in view of the low-level (but multicomponent), chronic exposures mostly encountered by human populations. Sorting out an epigenetic impact of environment on human germ cells with potential heritable consequences is not easy task, because of the need to control for genetic and cultural confounders. However, notably, a few human observational studies to date suggest that transgenerational effects exist that cannot easily be attributed to cultural and/or genetic inheritance (Pembrey et al. 2014).

Introduction

The preimplantation embryo, from the time of fertilization up until blastocyst formation before implantation into the uterine endometrium, undergoes an extensive series of cellular and molecular changes over a period of some 4–6 days that are critical for its future development. These changes include: activation of the new embryonic genome to replace the parental gametic genomes; resumption of cell cycling within the zygote from a period of arrest awaiting fertilization; and initiation of morphogenesis leading to the establishment of distinct true embryonic (future fetal) and extra-embryonic (future placental) cell lineages by implantation. Preimplantation morphogenesis results in a blastocyst, a spherical cyst of ~100 μm diameter, comprising (i) an outer layer of differentiated trophoblast (TE) epithelial cells, the progenitor of the placenta; (ii) a blastocoelic cavity generated by TE transport activity, and (iii) an internal cluster of relatively undifferentiated cells, the inner cell mass (ICM), eccentrically placed on the basal surface of the TE (**Fig. 1**). In the late blastocyst stage, the ICM segregates into the epiblast, the progenitor of the entire fetus, and the newly-differentiated primitive endoderm epithelial layer abutting the blastocoel which gives rise to the visceral endoderm yolk sac placenta.

This busy schedule of cellular and molecular activity underlying blastocyst morphogenesis unfolds in a relatively autonomous manner, broadly independent of environmental factors since it can occur in a simple culture solution if an energy substrate and protein source is present. This complex and coordinated intrinsic developmental program involves the generation of radial asymmetry within the embryo, the formation of the distinct cell types, and a series of important cell–cell interactions that collectively guide cell fate and differentiation, coupled with temporal regulation of gene expression (**Bedzhov et al., 2014**). The switch in states from parental gametes (sperm, egg) to being an embryo includes epigenetic reorganization of the new embryonic genome to ensure the different cell types formed throughout development express appropriate genes. Epigenetic reorganization in the early embryo comprises global changes in DNA methylation and histone modifications that collectively regulate the pattern of gene expression (**Messerschmidt et al., 2014**).

During the preimplantation period, the intrinsic developmental program can, however, be influenced by external environmental conditions such as the availability and type of nutrients, a wide range of growth factors, hormones, metabolites, and cytokines present within the mother's reproductive tract, or the chemical composition of culture medium in assisted conception treatment. Early embryos are equipped with an array of membrane receptors and transporters that allow for sensing of environmental conditions such as insulin, amino acids, and glucose. These factors are mainly but not exclusively maternal in origin, may derive from remote sites of synthesis delivered through the vasculature or generated locally such as from uterine endometrial glands. Their release is usually under the control of ovarian steroid hormones. Alternatively, factors may be embryo-derived, acting in an autocrine fashion on the developmental program. The paternal seminal plasma also contains factors that at least indirectly can modulate the developmental program (discussed later).

These environmental factors are primarily embryotrophic, acting as positive regulators on embryo morphogenesis and physiology, stimulating cell cycling, and blastocyst development and attendant cell biological processes (**Hardy and Spanos, 2002; Robertson et al., 2015**). For example, in mice, insulin and the insulin-like growth factors (IGFs) promote mitogenesis, blastocyst formation and embryo cell number particularly in the ICM, glucose uptake, protein synthesis and cellular endocytosis. The cytokine colony stimulating factor 2 (CSF2) acts similarly as a positive regulator of preimplantation development and proliferation in a range of species leading to increased cell number and formation of blastocysts. Transforming growth factor alpha (TGF α) also stimulates development and blastocyst expansion including suppression of apoptosis. In contrast, tumor necrosis factor alpha (TNF α) slows development and increases apoptosis. The phospholipid, embryo-derived platelet activating factor (ePAF), is produced and released by the embryo after fertilization, binds extracellular albumin and acts in an autocrine way to stimulate embryo metabolism and developmental rate. ePAF production by embryos in culture medium and its autocrine activity acts to improve group culture of embryos over singleton culture. Chemokines are also critical in the process of immune tolerance of the mother toward the paternal antigens present in the embryo, coordinating maternal-embryo cross-talk to permit endometrial invasion of the TE derivative cells to occur at implantation—a dialogue that can prevent miscarriage (**Robertson et al., 2015**). Conversely, embryo development outside of the natural maternal environment and lacking ready availability of these stimulatory factors as during *in vitro* culture can reduce developmental progression. In addition, there is increased risk of production of reactive oxygen species (ROS) damage if environmental oxygen level is atmospheric, above that present *in vivo*.

One of the most exciting discoveries in reproductive biology in recent years is that environmental conditions may not be restricted to influencing the preimplantation developmental program in just the short-term but may impose changes in the embryo that persist throughout gestation and into postnatal life (**Fig. 2**). Such examples of longer-term environmental changes mediated during early embryogenesis may alter the growth trajectory during fetal development, disturb metabolic homeostasis, and associate with health and disease risk into adulthood. At one level, this interaction between embryo and environment can provide *plasticity* to

Fig. 1 Developmental milestones during mammalian preimplantation embryo development. The early embryo undergoes cellular and molecular events that are critical for a successful pregnancy. The preimplantation embryo is highly responsive to the environmental milieu present in the reproductive tract. Reproductive tract is representative of rodent and ruminant species.

the developmental program, allowing the early embryo to respond to prevailing environmental conditions and to optimize development accordingly to support survival of offspring. Alternatively, the environmental cues may perturb the developmental program such that changes represent deficiencies in cellular function.

These longer-term environmental effects on the preimplantation embryo are evident *in vivo* in response to the quality and type of maternal nutrition and her health and physiology at the time of conception. They are also apparent in response to *in vitro* culture conditions as occurs during assisted conception treatment. Such enduring effects are commonly known as *periconceptional developmental programming* and associate with a wider phenomenon now known as the “*Developmental Origins of Health and Disease*” (DOHaD). This concept proposes that poor conditions *in utero* mediated through maternal undernutrition and adverse health can disturb fetal development and be the forerunner of disease risk in later life, notably cardiovascular, and metabolic conditions (Barker and Thornburg, 2013). Classic epidemiological evidence in support of the DOHaD concept comes from the findings in several human population studies that low birth weight is a major predictor of hypertension and metabolic syndrome occurring in later adulthood. Below, we consider different examples and associated mechanisms by which environmental exposure to early embryos impose lifetime effects on health.

Effects of Maternal Nutrition and Metabolism on Preimplantation Embryos

Maternal Undernutrition

There is growing evidence that maternal undernutrition affects the development of the early embryo and with long-term consequences. For example, in a human famine dataset, generated following the 5-month Dutch Hunger Winter during WW2, those

Fig. 2 Long-term effects of the preimplantation environment. Maternal factors can alter the microenvironment of the ovary and the reproductive tract which in turn can impact the early embryo. Paternal factors can affect the preimplantation embryo via maternal tract alterations exerted by seminal plasma. Exsitu development of the preimplantation embryo during assisted reproduction can compromise its viability. All these environmental influences can result in the expression of adverse phenotypes during postnatal life.

people experiencing the famine in utero during *early* gestation, compared with those exposed during *late* pregnancy, developed more severe cardiovascular, metabolic, and neurological deficits in adulthood (Roseboom et al., 2011). In another context, in The Gambia, where seasonal variation in food availability and consumption can also lead to chronic disease in later life, poor nutrition experienced by mothers around conception may have a significant influence. In both of these human examples, poor maternal nutrition affects the pattern of epigenetic reorganization of the genome during embryogenesis and likely contributes to the longevity of the consequences. In the Dutch Famine, gene pathways regulating growth and metabolism become differentially methylated in those experiencing famine during their early development and such changes persist into adulthood. In the Gambian study, the quality of maternal nutrition at conception alters the DNA methylation epigenome, a condition still evident in late childhood (Dominguez-Salas et al., 2014).

Animal models permit more focused studies to identify the mechanisms and consequences of poor maternal nutrition on the early embryo. This is best exemplified in a rodent model in which a maternal low protein diet is provided during only the preimplantation period with normal diet at other times and postnatally (known as Emb-LPD treatment). This treatment caused postnatal offspring to exhibit abnormal growth and adiposity with increased risk of cardiovascular and metabolic disease, especially in females (Watkins et al., 2008). How does this long-term phenotype emerge following this short duration of maternal undernutrition around the time of conception? Emb-LPD has been shown to reduce insulin and amino acid levels in the maternal circulation and this leads to changes in the amino acid composition present in the uterine fluid where embryos reside prior to implantation. Insulin and the branched-chain amino acids (BCAAs) leucine, isoleucine and valine are used by cells as biosensors to set the growth rate through the mTORC1 signal pathway, a master growth regulator integrating nutrient availability and growth. In Emb-LPD blastocysts, mTORC1 signaling is significantly reduced under these low insulin and BCAA conditions indicating this pathway is utilized to sense nutrient availability for growth (Eckert et al., 2012).

This preimplantation nutrient-sensing mechanism subsequently regulates the growth trajectory for fetal development by manipulating the rate of ribosome biogenesis. Thus, if nutrient availability remains low, ribosomal RNA expression is suppressed in embryonic/fetal somatic tissues to restrict growth. However, if nutrient availability increases (as occurs postblastocyst stage in Emb-LPD treatment), ribosome biogenesis is increased beyond that of controls. This capacity for preimplantation experience to manipulate ribosome biogenesis occurs not only during pregnancy but also throughout the lifetime and represents an opportunistic response to “catch up” growth as conditions improve (Denisenko et al., 2016). This coordination between nutrient levels and ribosome biogenesis is regulated epigenetically, with methylation on the ribosomal DNA genes being increased to suppress RNA polymerase 1 binding and rRNA expression in conditions of low nutrients, and vice versa in high nutrients. Along with mTORC1, evidence indicates nutrient sensing to manipulate ribosome biogenesis is achieved through the ribosomal protein, Rrm3 that associates with the mTORC1 complex (Denisenko et al., 2016).

The mouse Emb-LPD model demonstrates a second mechanism activated in the preimplantation period to protect growth under conditions of poor maternal nutrition. Here, the extraembryonic (placental) cell lineages respond to poor diet by increasing the

efficiency of maternal nutrient delivery during pregnancy. Thus, Emb-LPD blastocyst trophectoderm increases proliferation and the rate of cellular endocytosis, thereby capturing more maternal nutrients. The endocytosis response is comprehensive and involves increased expression of endocytosis membrane receptor (megalin), increased uptake of protein ligand and increased collective numbers of lysosomes to digest maternal nutrients. This compensatory mechanism is induced by embryo sensing of reduced environmental insulin and BCAA levels and is regulated by the RhoA GTPase molecular switch which modulates the actin cytoskeleton to promote endocytosis (Sun et al., 2014). A similar stimulation of endocytosis occurs with increased proliferation within the primitive endoderm lineage, here associating with epigenetic modification through histone deacetylation of the Gata6 transcription factor promoter. Collectively, these early extra-embryonic adaptations to poor diet persist beyond the preimplantation period and promote nutrient delivery via the main chorioallantoic placenta and yolk sac placenta throughout gestation (Watkins et al., 2008).

The Emb-LPD model therefore demonstrates distinct embryonic and extra-embryonic compensatory mechanisms whereby a low nutrient preimplantation environment activates developmental plasticity to facilitate survival of the conceptus. These responses, whilst promoting fetal growth, do associate with later cardiovascular disease since they are suited for a nutrient-deprived environment and so are maladaptive for the nutrient-rich conditions experienced after the dietary treatment leading to increased mass, adiposity, and chronic disease. Related studies in sheep whereby below-maintenance feeding of ewes during only the periconceptional period have shown a similar legacy with an altered growth trajectory and adverse cardiovascular and metabolic health in later postnatal life. The importance of altered epigenetic programming has also been clearly demonstrated by periconceptional restriction in sheep B vitamin micronutrients that, through 1-carbon metabolism, provide the methyl donors required for DNA methylation. This treatment significantly alters the offspring epigenome and occurs in association with cardiometabolic abnormalities (Sinclair et al., 2007).

Maternal Obesity and Overnutrition

The global epidemic of overnutrition and obesity is known to affect reproduction by reducing fertility and disturbing fetal metabolism such that children of obese mothers often become obese themselves. This vicious cycle can be traced from the typical high BMI and elevated systemic glucose and insulin levels in mothers driving excess fetal growth and adiposity, often coupled with allergic and atopic disturbance, leading to overweight and cardiometabolic disease risk in offspring.

Focused human and animal model studies have shown that oocyte maturation and the early embryo can be particularly sensitive to maternal obesity and overnutrition. Ovarian follicular fluid becomes richer in metabolites such as insulin, lactate, and fatty acids in overweight mothers and these may subsequently accumulate within oocytes and persist in early embryos where they cause metabolic disturbance (Robker et al., 2009). Firstly, mitochondrial activity is affected with abnormal morphology, cristae structure and membrane potential leading to increased mitochondrial biogenesis to compensate (Lane et al., 2015). Second, the rich maternal metabolite environment causes oxidative stress in oocytes and embryos with the elevated lipid content leading to activation of endoplasmic reticulum stress where protein misfolding occurs during biogenesis, associating with metabolic disorders. These effects lead to reduced embryo development rates and potential. Moreover, transfer of animal embryos from obese mothers, or after in vitro culture in rich nutrients, to lean controls can lead to fetal overgrowth, malformations and glucose-insulin resistance, mimicking the intergenerational conditions found in humans despite the absence of maternal gestational obesity. Thus, environmental exposure to overnutrition around the time of conception and preimplantation development is sufficient to compromise next generation health (Lane et al., 2015).

Effects of In Vitro Assisted Conception Treatments on Preimplantation Embryos

The remarkable success of assisted reproductive treatments (ART) to overcome human infertility is well recognized with several million children born worldwide. Given the influences described above on maternal nutritional effects on the early embryo and their legacy over the lifetime, it is therefore pertinent to evaluate the safety of current techniques used in clinical embryology. Such analysis is complex given the inherent poor fertility of parents involved which may be directly affecting embryo potential, the diversity in patient demographics that may also be influential, and the wide range and changes in procedures used in ART over the years complicating any causal relationships that may be identified. Animal models of ART treatments have therefore been invaluable where many of these variables can be controlled.

Despite these caveats, when considering human ART outcomes after single embryo transfer, several long-term deficiencies compared with natural pregnancies have been identified. These include increased incidence of perinatal complications such as congenital abnormalities, low birth weight, and increased mortality. The effect of embryo culture medium is the most widely studied aspect of human ART postnatal outcomes. Whilst the chemical composition of commercial culture media used are not disclosed, it is apparent, particularly from a randomized control trial, that different culture media impose significant differences in birth weight and this distinction is maintained through early childhood (Kleijkers et al., 2016).

The health of ART children and adults has been followed up in epidemiological studies. These indicate cardiovascular abnormalities are increased in ART offspring including raised blood pressure, altered blood flow rates and vessel thickness, heart shape and size which can in some cases be traced back to defects occurring during the pregnancy period. ART children also exhibit metabolic risks including increased glucose-insulin resistance, increased plasma lipids, and raised adiposity (Sunde et al., 2016). The use

of mouse models with more rigorous experimental design has confirmed an increased risk of cardiometabolic long-term effects such as hypertension and insulin resistance in adult offspring.

The basis for ART environmental effects on embryo potential appear similar to those found from in vivo nutritional studies with evidence of epigenetic disturbance as an early mechanism. ART children have increased risk of rare disorders in imprinted genes which regulate gestational growth. These involve abnormal DNA methylation and such effects can be identified in human embryos. Animal models also show embryo culture causes loss of the normal mono-allelic expression of imprinted genes in embryos and subsequent placental and fetal tissues after transfer. Epigenetic disturbance of imprinted genes also appears causal in “large offspring syndrome,” a condition identified following domestic animal embryo culture in serum-containing medium before transfer to recipients and the occurrence of abnormal excess perinatal weight.

Embryo culture may initiate compromised development because of the absence of natural maternal factors that may occupy the maternal reproductive tract in vivo (see [Introduction](#)). Thus, the cytokine CSF2, shown to have a stimulatory effect on preimplantation survival and morphogenesis, also provides protection for adverse long-term developmental programming when included as a supplement in embryo culture before transfer in mice and sheep. Inclusion of CSF2 to mouse culture medium before transfer protected against abnormal placental structure and fetal growth which occurred in its absence ([Robertson et al., 2015](#)).

Other Models of Environmental Impact on Preimplantation Development

Environmental conditions inducing early embryo programming appear to be broad. For example, maternal systemic inflammation and sickness by endotoxin treatment around the time of conception, inducing a transient pro-inflammatory environment, altered blastocyst cell numbers in mice but, unlike the nutritional models discussed above, had no clear effects on offspring cardiometabolic health. In contrast, the maternal inflammatory condition induced altered programming of adult offspring innate immunity and responsiveness to administered endotoxin such that the immune response was blunted ([Williams et al., 2011](#)). This suggests the preimplantation inflammatory environment had programmed increased tolerance in offspring, perhaps a compensatory mechanism suited for a predicted pathogen-rich environment.

In other studies, a paternal influence on embryo environmental programming has been identified mediated by the composition of seminal plasma. The plasma has traditionally been viewed as a transient nutritious and stabilizing environment for sperm during mating but recent research has demonstrated that it acts within the maternal tract to stimulate both the mother’s immunological response to maintain pregnancy and, either directly or indirectly, the embryo itself, affecting placental phenotype and postnatal offspring metabolism and cardiovascular health ([Bromfield et al., 2014](#)). This paternal environmental influence via seminal plasma on embryo developmental programming adds to the growing body of knowledge that paternal physiology and lifestyle (diet, BMI, obesity) can affect not only his fertility but the development and health of his offspring ([Lane et al., 2015](#); [Watkins et al., 2017](#)).

Conclusion

We have seen that the environment of the early embryo has critical roles in developmental potential, not only facilitating early morphogenesis but also modifying placental, fetal, and postnatal phenotype with important health implications. This argues for exceptional care to be taken in protecting that environment from adverse conditions, a time when the pregnancy will not be known. For example, there is a case for preconception preparation for pregnancy for both partners in terms of weight, physiological state and wellbeing ([Barker et al., 2013](#)). ART practice needs to recognize this phenomenon both in patient condition and also the safety of embryo culture and manipulation conditions. The same is true for agricultural applications using reproductive treatments. We are still in our infancy in terms of understanding the mechanisms by which embryo environment can have such a profound effect across the lifespan and so more research is warranted.

Reproductive medicine has evolved rapidly over the last decades, and evaluation and treatment of the female and male have transformed apace. Reproductive medicine in the female in Volume 4 starts with the evaluation of the female in the infertile couple. The diagnostic work-up includes the clinical aspects and the investigation of reproductive endocrinology, reproductive genetics, reproductive tract microbiota, coagulation, as well as the visuals such as imaging and reproductive endoscopy. Then, the most prevalent medical conditions that affect reproductive medicine are considered ranging from endocrine disorders to congenital, infectious, or benign tumors. Oncofertility is the next section that deals with the reproductive treatment and expectations in women suffering malignant tumors of the reproductive tract. Then, medical and surgical treatments of the indicated medical conditions are presented to the reader. Finally, the psychological aspects of the female reproductive medicine as well as legal and ethical aspects are considered.

Reproductive medicine in the male in Volume 4 begins with the evaluation of the male with presumed reproductive dysfunction and includes topics ranging from interrogating the biological system to the organs that are directly involved in reproduction. The volume continues with the effects of the environment on male reproductive potential and proceeds to a thorough treatment of the genetic basis for reproductive diagnosis and therapy in the male. The succeeding sections in the volume present medical conditions that affect reproductive potential and then focuses on therapy, first medical and then surgical. Finally, critical issues in mental health, ethics, and the law are addressed, and the male portion of the volume concludes with benign and malignant diseases affecting male fertility.

EVALUATION FEMALE FERTILITY

Clinical Evaluation of the Subfertile Female

In fertile couples, the monthly gestation rate is between 20% and 25%, reaching a rate of 84% in the first year of sexual relations. These rates are affected by several prognostic factors, the most important being the age of the woman ([Remohí et al., 2017](#)). Fertility in women is reduced by half at age 35, and declines more quickly after 40 years. In men, the decline begins at age 35, and decreases by 23% per year ([Remohí et al., 2017](#)). An estimated 15%–30% of couples will have fertility problems ([Gelbaya et al., 2014](#)).

Infertility is the inability of a couple to conceive after 1 year of unprotected sex. To enable such couples to produce offspring, a basic study of sterility is recommended in both partners after this time period. Yet, for some couples an earlier infertility study can be beneficial. Earlier initiation of the workup is recommended for women over 35; recurrent pregnancy loss; female antecedents of pelvic surgery or pelvic infectious disease; women with irregular menstrual cycles, amenorrhea, or oligomenorrhea; couples with genetic diseases; or a suspicion of male subfertility (history of surgery or urogenital pathology, history of sexually transmitted diseases) ([Remohí et al., 2017](#)). It is important to differentiate primary infertility (couples without previous offspring) from secondary infertility (couples that have managed to conceive in the past) since secondary infertility typically has a better reproductive prognosis ([Remohí et al., 2017](#)). We define recurrent pregnancy loss as the occurrence of two or more failed pregnancies ([ASRM, 2008a](#)).

Basic Study of the Infertile Woman

It is advisable to study both partners simultaneously, but in this article we will focus on the basic study of infertility in women.

Clinical History and Basic Exploration

The following information should be collected in the first visit with the patient to identify symptoms that explain the infertility or assess the availability of inheritable and/or prognostic factors to guide the selection of additional tests ([ASRM, 2015b](#))

- *Personal history*: Age, allergies, age of menarche, age of onset of development of secondary sexual characteristics, menstrual pattern, history of contraceptive methods, history of pathologies, previous surgeries, history of sexually transmitted diseases, hormone-dependent diseases (thyroid diseases, hirsutism), autoimmune diseases, symptoms related to endometriosis (dyschezia, dysmenorrhea, intercourse pain) and consumption or exposure to toxic drugs.
- *Family history*: Early menopause, genetic or chromosomal diseases, and reproductive problems.
- *Reproductive history*: Length of infertility or recurrent pregnancy loss, primary or secondary infertility, history of reproductive treatments, history of previous pregnancies, and coital frequency.
- *Physical examination*: Body mass index (BMI), blood pressure, secondary sexual characteristics, vaginal and cervical examination, and phenotypic characteristics.
- *Transvaginal ultrasound*: Uterine, annexial, and pelvic assessment.
- Karyotyping.

Principal Causes of Infertility in Women and Additional Tests

The study of infertility should be oriented to be as cost-efficient as possible while avoiding a delay in diagnosis and treatment. In addition, to enable selection of appropriate diagnostic tests, the following should be considered: patient preferences, reproductive age, length of infertility, primary or secondary infertility, clinical history, and physical examination findings ([Table 1](#)).

*The authors contributed equally.

Table 1 Principal causes of infertility in women and appropriate diagnostic tests

<i>Principal causes of infertility in women</i>	<i>Diagnostic tests</i>
Ovulatory function and ovarian reserve	• Clinical signs of abnormal menstrual cycle. Vaginal-Ultrasound. Plasma progesterone levels (between 21st and 22nd day of cycle), urinary luteinizing hormone (LH) near the middle of the menstrual cycle. • Basal FSH, anti-Müllerian hormone (AMH), antral follicle count (AFC)
Assessment of tubal factor	• Hysterosalpingography (HSG), hysterosonosalingoscopy (HSSG), anti-<i>Chlamydia trachomatis</i> antibodies, laparoscopy (LPS)
Study of the cervical canal and uterine cavity	• Three-dimensional ultrasound, hysteroscopy (HSC)

Evaluation of Ovulatory Function

Ovulatory dysfunction is present in 15% of couples, but affects up to 40% of sterile couples. The most frequent clinical signs associated with ovulatory dysfunction are amenorrhea and oligomenorrhea. According to the World Health Organization (WHO), ovulatory dysfunction can be classified into seven groups (Table 2). Ovulatory dysfunction can also result from endocrine disorders (Cushing's syndrome, obesity, congenital adrenal hyperplasia, etc.) or certain medications (neuroleptics, antidepressants, antihypertensives, etc.).

Approximately 97% of women who have regular menstrual cycles (between 26 and 35 days) ovulate spontaneously. In these patients it is generally not necessary to perform diagnostic tests to confirm ovulation. A normal menstrual cycle has a peak of LH hormone between days 12 and 14 (considering day 1 as the day when menstruation starts) and the dominant follicle is ovulated 2–36 h later. The corpus luteum develops and begins to produce progesterone, the hormone needed for endometrial preparation for implantation. Ovulation is typically assessed by assaying plasma progesterone levels in the middle of the luteal phase or urinary LH near the middle of the menstrual cycle, or by transvaginal ultrasonographic visualization of the corpus luteum in the ovary. Plasma progesterone, determined between days 21 and 22 of the cycle, suggests ovulation has occurred if the levels are above 10 pg/mL. In contrast, LH levels typically peak in the urine between 24 and 36 h before ovulation. Importantly, these tests imply ovulation has occurred in the tested cycle but cannot be extrapolated to consecutive cycles (ASRM, 2015b).

Evaluation of the Ovarian Reserve

The ovarian reserve reflects the functional capacity of the ovary, that is, the number of follicles available at a given time (Remohí et al., 2017). As a woman ages, the quantity and quality of the gametes decreases and, consequently, so does the reproductive prognosis (Remohí et al., 2017). Ovarian aging usually results in objective endocrine and ultrasound changes.

Among endocrine markers, the most commonly tested are the basal level of follicle stimulating hormone (FSH) and the level of anti-Müllerian hormone (AMH), both of which are involved in folliculogenesis (ASRM, 2015a).

Basal FSH basal

Levels of FSH between the 2nd and 4th days of the cycle are used to assess ovarian reserve (Remohí et al., 2017). Levels > 10–12 IU/L are indicative of low reserve; however, instances in which normal levels of FSH occur along with estradiol levels above 60 pg/mL are also indicative of low reserve (Remohí et al., 2017). FSH levels are not stable over time, but they tend to present significant inter- and intra-cycle oscillations (Bungum et al., 2011).

Table 2 Classification of amenorrhea according to the WHO, 1970

<i>Category</i>	<i>Origin of the problem</i>	<i>Diseases</i>
GROUP I	Hypothalamus–pituitary axis failure	Anorexia nervosa, Kallman syndrome
GROUP II	Hypothalamus–pituitary axis dysfunction	Polycystic ovary syndrome (PCOS), hypothyroidism
GROUP III	Ovarian failure	Early ovarian failure
GROUP IV	Genital tract malformations or alterations	Rokitansky-Küster-Hauser syndrome, Asherman syndrome
GROUP V	Prolactinomas	Prolactin pituitary tumor
GROUP VI	Functional hyperprolactinemia	Maternal lactation
GROUP VII	Hypothalamus–pituitary tumors, non-prolactin secreting	Pituitary adenomas

The measurement of FSH has low sensitivity (10%–30%) for the diagnosis of low ovarian response (ASRM, 2015a). Indeed, it is common to detect normal FSH levels in patients who have low AMH levels and/or low antral follicle count (AFC). This finding reflects the fact that an increase in FSH levels is not evident until the ovarian reserve is markedly compromised; in contrast, AMH and AFC tend to decrease in earlier stages of ovarian reserve impairment. A prospective study that determined the live birth rate (LBR) in young subfertile patients (mean age 35 years) assessed correlations with elevated FSH and AMH levels, concluded that reproductive prognosis was directly related to AMH levels (> 1 ng/dL) but not FSH levels (> 12 IU/L). Despite elevated FSH levels in some patients, 67% achieved a pregnancy, of which 37% were spontaneous (Yarde et al., 2013). Thus, we conclude that measuring FSH offers a less reliable assessment of ovarian reserve in comparison with other markers, and its predictive capacity for pregnancy prognosis is low.

Anti-Müllerian hormone

AMH is produced and secreted into the bloodstream by the granulosa cells of the preantral and small antral follicles (4–8 mm) and it is responsible for the control and development of the ovarian follicles (Remohí et al., 2017). Currently, two analytical techniques are used to assess AMH levels: Elecsys® assay and Access® AMH Assay. A recent study compared the results of AMH levels obtained using each technique. The Access® technique produced AMH values that were 5%–15% higher than those measured by the Elecsys® technique, especially in patients with high AMH (Iliodromiti et al., 2017).

AMH concentration in blood has been related to the ovarian response to exogenous stimulation. When Elecsys® is used we consider levels between 0.7 and 1.3 ng/mL as predictive of poor response; levels above 3.7–4.6 ng/mL are indicative of hyperresponsiveness (Remohí et al., 2017) while with Access® the values are categorized as low (< 5 pmol/L), normal (5–15 pmol/L) and high (> 15 pmol/L).

There is no universal consensus on the pre-analytical conditions for AMH reference values. The first reports on AMH indicated that its levels were more stable than the levels of FSH, and that it could be measured at any time during the menstrual cycle. Yet, studies emerged to show that AMH levels change under certain circumstances, such as oral contraceptive use or administration of GnRH analogues (Bungum et al., 2016). Further, AMH levels can oscillate over phases of the menstrual cycle and between different cycles. A prospective study indicated that AMH levels increase in the late follicular phase (4–5 days before ovulation), and more markedly so after age 30 (Lambert-Messerlian et al., 2015).

Circadian variations have also been observed, with very low levels detected between 4:00 and 6:00 in the morning relative to the levels at 8:00 in the morning (Bungum et al., 2011). In a retrospective study that evaluated inter-cycle changes in AMH levels in the same individual, a variability of 20% was observed, highlighting the intra-individual variation, as opposed to the well-known variability linked to the analytical technique. The study also noted that 29% of cases had changes in their classification of ovarian reserve because of AMH variation (Bungum et al., 2016). These findings underscore the need for caution when giving reproductive counseling that considers only AMH levels.

The relationship of AMH values with reproductive prognosis is also controversial. A recent study found no statistically significant differences between the pregnancy rate in women without problems of fertility and their AMH levels (regardless of age) (Steiner et al., 2017). In contrast, another study observed that the reproductive prognosis in different age groups improves with AMH levels (Tarasconi et al., 2017). However, the same study found an inverse correlation between AMH levels and rates of spontaneous abortion. The authors hypothesized that low levels of AMH are a consequence of deficient production by defective follicles, giving rise to oocytes of poor quality. Thus, it is unclear whether AMH levels can be used to predict reproductive success (Steiner et al., 2017).

Antral follicle count

Although AFC is not the only ultrasound marker used to assess ovarian reserve, it has the best clinical predictive value (Remohí et al., 2017). Using a transvaginal two-dimensional (2D) ultrasound, usually in the early follicular phase (3rd to 5th day of the cycle), all follicles between 2 and 10 mm are counted in both ovaries. An AFC lower than 6–7 follicles is predictive for low ovarian response but does not predict reproductive prognosis. Three-dimensional ultrasound and volume calculations offer less inter-observer variability but do not improve clinical outcomes (Remohí et al., 2017). Further, the ovarian volume can be evaluated; values < 3 mL are related to low responses, while volumes > 6 –8 mL are associated with a hyperresponse (Remohí et al., 2017). Ovarian vascular flow, and specifically its absence, has also been described as a predictor of low response (Remohí et al., 2017).

In a prospective study comparing ovarian reserve markers, AMH and AFC were able to predict low ovarian response with high accuracy and independently of each other (Jayaprakasan et al., 2010). However, a recent randomized study concluded that AMH is not better than AFC for predicting ovarian response. In one study group, the dose of recombinant FSH (rFSH) was determined by the levels of AMH; this group contained more cases of low response (< 5 ovules obtained) than the group where the rFSH dose was calculated according to the AFC ($p < 0.001$) (Magnusson et al., 2017).

Assessment of Tubal Factor

The fallopian tubes are critical to the uptake and transport of gametes and embryo, sperm capacitation and fertilization process. These processes require an intact anatomical and functional structure. Tubal damage can be usually caused by an infection, endometriosis, or previous pelvic surgery, and tubal factor is a contributor in 14% of cases of sterility. Several tests are available for assessing the tubal factor.

Hysterosalpingography and hysterosonoscopy

HSG involves injecting radiopaque contrast through the cervix and following its passage through the tubes by radiography (Remohí et al., 2017). Compared to laparoscopy, HSG is simple, cost-effective, has minimal complications and does not require anesthesia. This technique has a sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) of 88%, 87%, 71%, and 94%, respectively (Luciano et al., 2013).

HSSG has a basis similar to HSG—retrograde injection of a liquid through the cervix and assessment of its passage through the tubes—but uses ultrasound rather than radiology. The first reports on HSSG highlighted limitations regarding the type of medium used (air with saline solution), which hindered the examination of the tubes and required that the technique only be performed by expert hands. The advent of new ecovisible media (gel or foam of hydroxyethylcellulose and glycerol) has increased the sensitivity and specificity of HSSG (75%–96% vs. 67%–100%, respectively) (Luciano et al., 2013). Further, the application of 4D technology to HSSG allows a 3D assessment in real or delayed time of the morphology of the uterine cavity and tubes and the presence of pelvic adhesions, thereby facilitating clinical interpretation. With the incorporation of this technology, the sensitivity, specificity, PPV, and NPV of the test are 93.8%, 92.2%, 90.5% and 82.1%, respectively (Wang et al., 2017).

Both scans have a risk of infection around 1%, which can be prevented with the administration orally of 1 g of azithromycin 12 h before the test. Although both techniques can be uncomfortable for the patient, HSG is usually more painful due to the peritoneal irritation produced by the contrast medium, and sometimes, the patient should require subsequent analgesic treatment.

Anti-*Chlamydia trachomatis* antibodies

The Bacterium *Chlamydia trachomatis* (CT) is mandatory intracellular and responsible for the majority of pelvic inflammatory diseases of bacterial origin worldwide. The overall prevalence in Europe is about 30% and the most new cases were diagnosed in patients between 15 and 49 years of age (WHO, 2016). CT usually produces an asymptomatic or subclinical infection, that if left untreated can lead to severe lesions in the tubal anatomy and physiology. Currently there are five methods for the confirmation of an active CT infection (Remohí et al., 2017), but the NAAT Test (nucleic acid amplification test) is considered by the WHO (2016), as the best diagnosis test because it is the most sensitive and specific than the others (93% and 99%, respectively). It is characterized by the rapid sequencing of DNA (by PCR) of the *Omp1* gene, responsible for the expression of the transmembrane antigen protein of *Chlamydia* (MOMP) (Chen et al., 2017a). This can be applied to samples from different locations (cervix, urine, vagina, urethra) and with good results (Remohí et al., 2017). The measurement of serum concentrations of anti-*Chlamydia* antibodies (IgG or IgA), is other test that is used to confirm an active CT infections, but in comparison with the NAAT test, its have a similar sensitivity, ($S = 95\%$); but its specificity is lower ($E = 43\%$ – 81%) (Sahi et al., 2017). On the other hand, we must emphasize that seroconversion of IgG and IgA by a CT infection usually lasts for years, even if the patient has been treated with an antibiotic and no longer has the infection (Taheri Beni et al., 2012). Therefore, its determination will help us to identify an active CT infection, but it will also inform us if the patient has been previously infected, arriving to provide a prognostic value on the current tubal status.

In a non-randomized retrospective study (Den Hartog et al., 2008), serological results were compared with the results of the HSG. In seropositive cases the rate of pathological HSG was 53%–60%, in comparison to 14% among seronegative patients.

Another study (Geisler et al., 2012) evaluated the S and E of a new diagnostic test (elementary body-based enzyme-linked immunosorbent assay, EB-ELISA) compared to other available tests (OmpA: major outer membrane protein peptide-based *C. trachomatis*-IgG and IgA ELISA and Medac Assay). Among antibodies most frequently positive after *Chlamydia* infection, the IgG subtypes IgG1 and IgG3 were the most predominant and stable in time; for IgA, only IgA1 showed a significant increase with respect to its other subtype (IgA2). The levels of these subtypes (IgG1, IgG3, and IgA1) were compared in patients with confirmed *Chlamydia* infection by nucleic acid amplification test (NAAT) at 0 and 6 months. In the study patients (NAAT-positive), 100% of the patients were positive for IgG1 and IgG3, whereas only 74% of patients were positive for IgA1. After 6 months the serological study was repeated; 100% of patients seropositive initially for IgG1 and IgG3 continued to be positive, while only 61% of the patients remained positive for IgA1. Thus, IgG1 and 3 are more stable over time than IgA (IgA1) and should be the preferred markers.

Importantly, patients seropositive for IgG1 or IgG3 for *Chlamydia* were shown to have a pregnancy rate lower than the control group (Steiner et al., 2015). In particular, a positive IgG3 test was associated with a decrease in the pregnancy rate from 38% to 26% ($p < 0.001$) and an increase in the risk of ectopic pregnancy from 4% to 11% ($p = 0.02$). However, despite these results, anti-*Chlamydia trachomatis* antibody testing has a limited clinical application and can be considered in questionable HSG, or as a screening for tubal injury.

Laparoscopy (LPS)

LPS is considered the “gold standard” in the diagnosis and treatment of tubal pathologies. This approach allows direct visualization of tubal morphology and can detect the presence of adhesions that may affect tubal flow. Incorporating the retrograde instillation of methylene blue (chromoperturbation technique) enables assessment of tubal permeability. However, LPS should not be considered as the first-line diagnostic approach, except in cases with suspicion of a pelvic (endometriosis) or tubal pathology (hydrosalpinx or sactosalpinx) that can be treated after diagnosis. Indeed, LPS is a costly, invasive technique that requires anesthesia and has a complication rate of 2%–3% (Gelbaya et al., 2014). Thus, its recommendation should be considered in light of other options.

Falloscopy, salpingoscopy, and fertiloscopy

The techniques of choice for tubal study only offer information on the permeability of the fallopian tubes, and do not guarantee that the inside of the tube is competent (Remohí et al., 2017). Falloscopy (transcervical tubal catheterization) consists of the

introduction of an endoscope through the tubal ostium, to assess its interior and repair the proximal blockage of the tubes to achieve pregnancy spontaneously or facilitate IUI. This is an invasive test that carries complications such as tubal perforation, and performing this test does not promote a pregnancy rate higher than that for IVF. In a recent meta-analysis, the rate of pregnancy after falloscopy was about 27% over the succeeding 6 months, but after that time the pregnancy rate decreased (De Silva et al., 2017). In contrast, the gestation rate with an IVF cycle would be around 35%.

Salpingoscopy (laparoscopic tubal catheterization) encompasses endoscopic study of the distal portion of the tube. It is a costly and invasive technique that requires performing a laparoscopy. In a retrospective study that compared the gestation rate with programmed intercourse or intrauterine insemination (IUI) according to the degree of tubal injury assessed by salpingoscopy, gestation rate was inversely related to the degree of injury in the tubal lumen ($p < 0.05$). In addition, the degree of injury was directly related to the presence of antibodies against *Chlamydia* (Nakagawa et al., 2010).

Fertiloscopy is similar to salpingoscopy but uses vaginal hydrolaparoscopy rather than abdominal laparoscopy. It is based on the creation of a hydroperitoneum through the vaginal cul-de-sac and introduces an optic to see the structures. This procedure does not require general anesthesia and can be performed on an outpatient basis. It has a complication rate of 3%, of which less than 1% are due to intestinal perforation (Wang et al., 2017).

Study of the Cervical Canal and Uterine Cavity

The uterine factor is usually present in 10% of cases of sterility. Myomas, endometrial polyps, and Müllerian malformations are some of the more common disorders that we observe in infertile women or those with recurrent pregnancy loss.

3D ultrasound

The introduction of 3D ultrasound into gynecological consultations has yielded improvement in the diagnosis of Müllerian malformation (Grimbizis et al., 2013) of the uterine cavity. With 3D echo we are able to visualize the coronal uterine plane, which aids the diagnosis of these malformations. The gold standard for diagnosis is magnetic resonance imaging (MRI), but 3D ultrasound presents high-quality images with a sensitivity, specificity, PPV, and NPV of 83%, 100%, 89%, 100%, respectively, comparable to MRI (Saravolos et al., 2016a).

3D ultrasound also enables calculations of endometrial volume, assessment of uterine vascularization, or assessment of the severity of adenomyosis (penetration and invasion by the glands and endometrial stroma within the myometrium). While attempts have been made to establish a relationship between endometrial volume and the pregnancy rate by embryo transfer, the results are contradictory. Some reports suggest that volumes less than 2 mL or greater than 8 mL are related to worse pregnancy outcomes, but other studies do not confirm these results. In fact, when the endometrial thickness is greater than 6.5 mm in the proliferative phase, the endometrial volume measured through virtual organ computer-aided analysis (VOCAL) does not show differences in the rate of evolutionary gestation in oocyte donation cycles, although those patients with very reduced endometrial volume seem to have worse reproductive results (Labarta et al., 2017). Studies of uterine vascularization (assessed by 3D ultrasound) in relation to pregnancy rate are inconclusive (Chen et al., 2017b). In the case of adenomyosis, there is increasing evidence of its negative effect during embryo implantation and perinatal outcomes (Puente et al., 2016).

Hysteroscopy (HSC)

HSC is the technique of choice for the study and treatment of pathologies or alterations of the uterine cavity, due to its high sensitivity and specificity. These alterations are related to worse reproductive prognosis. In a prospective study, women with Müllerian malformations (diagnosed by 3D ultrasound), with the exception of the arcuate uterus, had higher rates of abortion than patients with normal ultrasound (49.3% vs. 12.7%, respectively ($p = 0.05$)). In contrast, no differences were observed in pregnancy rates (Jayaprakasan et al., 2011). In a prospective study where the gestation rate was compared between a group with hysteroscopic myomectomy versus a conservative behavior, the gestation rate increased in the myomectomy group from 27% to 43% ($p < 0.05$) (Casini et al., 2006). In a Cochrane review, the observed improvement in the gestation rate was not statistically significant, although in the case of hysteroscopic endometrial polypectomy, was observed a statistically significant increase in the gestation rate ($p < 0.0001$) (Bosteels et al., 2013). Hysteroscopic treatment of intrauterine synechiae has also been associated to a significant decrease in the rate of abortion, implantation failure and ectopic pregnancy, but increase in the rate of ongoing gestation (Cholkeri-Singh and Sasaki, 2015).

An HSC would be indicated before embryo transfer in the case of diagnosing a refractory endometrium or insufficient thickness by ultrasound. Endometrial thickness should be evaluated by ultrasound before embryo transfer since an endometrium < 7 mm is associated with worse gestational outcomes (Garcia-Velasco et al., 2016). Among the causes of this alteration would be uterine surgery (dilation and curettage, myomectomies, etc.), as one of the main causes for the formation of endometrial adhesions, with Asherman's syndrome being the most serious form. Radiotherapy, Müllerian malformations, or endometritis can also cause insufficient endometrial growth (Garcia-Velasco et al., 2016). Endometritis is characterized by the presence of an endometrial inflammation that can be caused by an infection (mostly), the presence of a foreign body, radiotherapy, or the presence of adenomyosis. It is usually expressed as focal or diffuse hyperemia at the endometrial level, as visualized by HSC (Garcia-Velasco et al., 2016). In some studies, endometritis is associated with repeated miscarriages, implantation failures, and poor perinatal outcomes, but in others, no relationship has been observed (Puente et al., 2016).

More controversial is the systematic performance of an HSC before an IVF cycle. Clinical guidelines published by the National Institute for Health and Care Excellence (NICE) and the American Society for Reproductive Medicine (ASRM) (NICE, 2013; ASRM, 2015b) as well as recently published prospective and randomized studies (El-Toukhy et al., 2016; Smit et al., 2016), conclude that the performance of HSC before an IVF cycle in patients with normal ultrasound does not improve the LBR.

Final Considerations

The present review has critically appraised the current approaches to evaluating factors involved in female fertility. The selection of diagnostic techniques must be guided by clinical wisdom. As in any clinical work-up process, the number and order of the examinations should also adapt to the patient's profile and preferences.

The initial interview enables the clinician to identify some "clues" orienting to a priority evaluation of a given factor. Age above 35 makes a thorough evaluation of ovarian reserve mandatory, even with a regular menstrual pattern. Similarly, the pre-existence of any event related to peritoneal health requires tubal evaluation beyond patency tests. Yet, the evaluation strategy should also adapt to the potential treatments that the couple will need and accept. The findings obtained in a "first round" of examinations will also guide the aspects to be evaluated in depth to enable the best chances of reproductive success.

Introduction

Female reproductive medicine is undoubtedly one of the fields of medicine that has experienced a greater progression in recent years. Therefore, having a precise control of the changes that take place in the female reproductive system in a physiological way or in the course of techniques of assisted reproduction has become an authentic necessity. Nowadays, different diagnostic techniques in the study of female reproductive medicine are available, such as magnetic resonance, tomographic imaging, laparoscopy, hysteroscopy and ultrasound. The anatomical study of the female's internal genital organs by ultrasound has become a standard practice today. Ultrasound allows us to study both the normal anatomy and its pathology, in an innocuous, cheap and well tolerated way. Therefore, reproductive medicine and ultrasound are intimately linked, allowing us, for example, to obtain very realistic images of fetal intrauterine development.

In this article we will show images that undoubtedly illustrate the above mentioned, allowing the reader to understand the numerous applications of ultrasound as well as other diagnostic imaging techniques in reproductive medicine.

Normal Menstrual Cycle

Female menstrual cycle lasts 28 days with ovulation typically occurring on day 14. After ovulation the corpus luteum develops in the ovary and produces progesterone, this environment allows the endometrium to enter in a secretory phase and to become receptive to the implantation of an embryo. This stage is known as "implantation window" (phase in which the endometrium is receptive to nest a gestation).

Transvaginal ultrasound provides a precise approach of uterine and ovarian size and morphology scrutiny, as well as follicular and endometrial development during the menstrual cycle. Pelvic ultrasounds are performed using both the transabdominal and transvaginal approaches. However, transvaginal ultrasound customarily provides more accurate images of female pelvic organs, since the ultrasound probe lies nearer to these organs. Transvaginal ultrasound also easily depicts changes in the morphological appearance of both the ovary and endometrium due to periodic fluctuations in female hormones secretion (FSH and LH).

In the first days of the cycle, FSH levels are elevated in order to incite follicle development. During this cycle period all the follicles in the ovary measure less than 10 mm and are known as antral follicles. On the other hand, the immediate postmenstrual uterine endometrium is thin. With cycle progression, a dominant follicle is selected to be ovulated while the others undergo atresia. The dominant follicle has a progressive growth, reaching a diameter of 18–27 at the moment of ovulation. Under the influence of increasing estradiol levels, endometrial proliferation appears, this is depicted as a thickening of the endometrium (the so-called trilaminar endometrium).

After ovulation the follicle is transformed in corpus luteum, characterized by a rich vascularization. The post-operative endometrium, under the stimulus of progesterone secreted by corpus luteum, is represented by the loss of the trilaminar appearance and the development of a uniform band (Fig. 1).

Gynecological Pathologies

The different imaging techniques employed in the study of gynecological disease allow us to obtain accurate images of numerous benign and malignant pathologies. Next we will perform a vision of the most relevant pathologies in the different parts of the female anatomy.

- *The uterus.* Uterine fibroid or myoma is the most common benign tumor of the female genital tract. The prevalence of myomas peaks during the fourth decade. The symptomatology of this uterine tumor is related both to its size and location. It appears as a solid myometrium-dependent tumor. Ultrasounds give us the opportunity to diagnose, classify (intramural, subserosal and submucosal) and control their evolution (tumor growth) in an easy way. Magnetic resonance imaging is a precise method to define the size, number and location of the myomas in selected complex cases (Fig. 2).

Congenital anomalies of the female tract usually involve the uterus and the cervix. The diagnosis and precise classification of these congenital uterine anomalies is clinically relevant because of the high associated risk of infertility, endometriosis, and miscarriage. Imaging plays an essential role in its identification and treatment planning. Currently, magnetic resonance and 3D-ultrasound imaging are the preferred means of evaluation due to its ability to simultaneously assess the uterine fundus and cavity. Therefore, by assessing the internal and external contours, 3D-ultrasound and magnetic resonance are able to discriminate between different congenital uterine anomalies (Fig. 3).

Fig. 1 Menstrual cycle control. Evolutionary control of the menstrual cycle by ultrasound.

Fig. 2 Myoma or uterine fibroid. The myoma or uterine fibroid is the most frequent gynecological tumor, its assessment with different imaging techniques is of great relevance for its diagnosis and evolutionary control.

- *The endometrium.* Its ultrasonographic appearance as well as its thickness will depend on whether the patient is at a reproductive age or at a post-menopausal condition. The endometrium appears thin just after the menstruation and in menopause. However, it will become progressively thicker as the menstrual cycle progresses (the proliferative phase) and especially after ovulation (the secretory phase). 3D-ultrasound permits to analyze the endometrial volume, a precise parameter linked to endometrial receptivity in assisted reproductive treatments (Fig. 4).

A common benign endometrial pathology, causing abnormal uterine bleeding, is the endometrial polyp that appears as a nodular protrusion on the endometrial surface. The diagnosis of suspicion is firstly established with transvaginal ultrasound, and later confirmed by hysteroscopy (a fine telescope with a light and camera at the end). In addition, hysteroscopy allows its resection using scissors or an electric scalpel giving the opportunity of a posterior histological evaluation (Fig. 5).

Fig. 3 Congenital uterine malformations. The incorporation of three-dimensional ultrasound and resonance in the diagnosis of congenital uterine malformations has made it possible to differentiate precisely the septal and bicornuate uterus.

Fig. 4 Menstrual cycle ultrasound. Contribution of 2D and 3D ultrasound to the study of endometrial development during the menstrual cycle.

- *The cervix.* Nowadays ultrasonographic imaging of the uterine cervix is an essential part of preterm delivery risk assessment by measuring the cervical length. The shortening of the cervical length and the presence of the prolapsed membranes inside are signs of premature labor (**Fig. 6**).
- *The fallopian tube.* Hydrosalpinges are fallopian tubes that are blocked at their distal termination and distended with fluid. On the other hand, salpingitis (the acute infection of fallopian tubes) is known as a cause of tubal damage and of later hydrosalpinges. Development. These tubal pathologies are directly related with infertility. Using transvaginal ultrasound or magnetic resonance, the appearance of hydrosalpinx is that of a cystic adnexal mass (**Fig. 7**).

Fig. 5 The Endometrial polyp is one of the most frequent gynaecological pathologies. It's diagnostic assessment is possible thanks to ultrasound and hysteroscopy.

- *The ovaries.* Ovaries modify its aspect throughout the menstrual cycle. Antral follicles are small (about 2–9 mm in diameter) and we can count them with ultrasound during the early proliferative phase. The amount of these follicles along with female age and anti-Mullerian Hormone (AMH) determination (a protein hormone produced by the granulosa cells within the ovary) are by far the best tools that we have for assessing ovarian reserve. Ovarian reserve testing can tell us quite a lot about the remaining quantity of eggs a woman has. Moreover, it informs us about the probable response to ovarian stimulating drugs. This count has been facilitated with the introduction of three-dimensional ultrasound, since it give us the possibility to count the antral follicles in an automatic way (Fig. 8).

Gynecological pathology affecting the ovaries includes endometriosis (growth of endometrial tissue outside the uterus, especially in the pelvic cavity as in the ovaries), and ovarian tumors (both benign and malignant). Endometrioma (ovarian endometriotic cyst) is a common finding in the infertile patient. The typical ultrasonographic appearance is an unilocular cyst with internal homogeneous low-level echogenicity. 3D-ultrasound represents an opportunity to precise the diagnose of ovarian endometriomas due to its ability to perform multiple sections of this ovarian mass (Fig. 9).

Polycystic ovary is one of the most common endocrine disorders impairing females fertility. Major features of this condition include menstrual dysfunction, anovulation and signs of hyperandrogenism. Transvaginal ultrasound is considered the gold

Fig. 6 The measurement of the uterine cervix plays an important role in the diagnosis of the threat of premature labor.

Fig. 7 Pathology fallopian tubes. The pathology of the fallopian tubes determines the fertility of women. The diagnosis of a hydrosalpinx is possible thanks to the different imaging techniques available today.

Fig. 8 Evaluation of the reserve of antral follicles using 2D and 3D ultrasound.

Fig. 9 Benign and malignant ovarian pathology. Evaluation by ultrasound and laparoscopy.

standard in the diagnosis of this disease. Classical features (presence of > 12 follicles per ovary and ovarian volume greater than 10 cm^3) can affect either one or both ovaries. 3D-ultrasound represents a major advance in the diagnosis of polycystic ovary as it provides a clear vision of the rich follicular endowment characteristic of this endocrine pathology (**Fig. 10**).

Reproductive Medicine

Assisted reproductive techniques are generally employed for infertility treatments. These techniques include in vitro handling of both human oocytes and sperm. Furthermore, once fertilized the ovule, it allows the control of early embryonic development with the objective of achieving pregnancy and live birth. In order to enhance the results of these procedures, recruitment of multiple follicles is habitually required and this is reached by controlled ovarian stimulation with hormones (FSH and LH). Transvaginal ultrasound is the diagnostic technique used to control ovulation induction within the cycles of assisted reproduction. It allows us to handle follicular and endometrial development, deciding the precise moment to trigger ovulation and thereafter to transfer the embryos under ultrasound guidance.

Fig. 10 The polycystic ovary is the most frequent cause of chronic anovulation. This ovary is characterized by its large volume and large reserve of antral follicles.

Fig. 11 Control of ovulation induction by ultrasound. We can assess the number of follicles, their size and the ovarian volume.

Ovarian hyperstimulation syndrome is an iatrogenic complication of assisted reproduction technology. The syndrome is characterized by cystic enlargement of the ovaries and the presence of fluid shift from the intravascular to the third space due to increased capillary permeability. Its occurrence is dependent on the administration of human chorionic gonadotrophin (hCG). Since it is a potentially dangerous pathology, its prevention and evolutionary control relies in an appropriate diagnostic ultrasound (**Fig. 11**).

Early Pregnancy Scan

Undoubtedly, the most fascinating application of imaging techniques in reproductive medicine is the vision of the beginning of life. A pregnancy can be viewed as early as 5 weeks from the first day of last menstrual period using transvaginal ultrasound. Since that moment, a dizzying career begins in embryonic development, that has a precise chronology during the first 12 weeks (**Fig. 12**).

EARLY EMBRYONIC DEVELOPMENT

Fig. 12 Embryonic development. Early embryonic development. Its visualization thanks to the three-dimensional ultrasound is of great help.

Subsequently, the vision of fetal development is crucial to ensure its correct development, being the ultrasounds the main diagnostic tool in this field of medicine (Fig. 13).

The 3D ultrasound development has led a great improvement in the vision of the early stages of embryonic growth. Nowadays we have multiple 3D ultrasound modalities that allow a detailed view of embryonic and fetal development (Table 1).

Highlights in this cast of 3D modes is the HD-live mode that give us the opportunity to modify the light bump in order to get a better view of the gestation. The TUI (tomographic ultrasound imaging) mode permits to obtain multiple planes of the structures studied. The AVC (automatic volume calculation) mode permits us to perform an automatic count of antral follicles. Moreover, the

Fig. 13 Late fetal development. Its control by means of ultrasounds allows to monitor the correct fetal development.

Table 1 Chronology of embryonic development during the first 12 weeks of gestation

5 Weeks	We visualize the gestational sac, which grows at a rate of 1.15/mm per day, with the yolk sac and embryo growing at a rate of 1 mm per day. In these early stages we can see the omphalomesenteric duct that connects the yolk sac with the umbilical cord.	
6 Weeks	This week begins a rapid development of the embryo, clearly differentiating a cephalic and caudal pole. The amnion membrane covers the entire embryo and the yolk sac is located extra-amniotic in the extraembryonic coelom.	
7 Weeks	The embryo continues its rapid growth. In this week the limbs differ. Also, the embryo initiates the achievement of small movements between the cephalic pole and the caudal pole. The space between the chorion and the amnion called extra-embryonic coelom persists.	
8 Weeks	During this week we can distinguish with great precision the fetal head. The embryo now realizes movements more and more complex. In the limbs, the hands can be visualized. At the umbilical level a physiological herniation occurs.	
9 Weeks	In this week the embryo already measures 25 mm. As characteristic features of this week highlight the visualization of the stomach and urinary bladder. This is the result of the onset of swallowing and renal function with urine production.	
10 Weeks	In this week the embryo measures 35 mm and we can distinguish in the face the eye orbits, the nose and the mouth. The physiological herniation begins to reverse, establishing the base of the umbilical cord at fetal level.	
11 Weeks	In this week the embryo measures 45 mm and we are able to differentiate the fingers and toes. The coiling development within the umbilical cord (one new spiral coil and one extra-centimeter in length for every gestational week approximately) appears to be obvious.	

(Continued)

----------	--	---

advent of radiance or silhouette mode as a new tool in ultrasound diagnosis is intended to assist by generating additional realistic image visualization and a better distinction among different tissues (**Fig. 14**).

Embryo and Fetal Pathology

Prenatal diagnosis techniques allow an early detection of fetal pathology by studying the thickness of the nuchal translucency, the presence or absence of the nasal bone, and the ductus venosus. Nuchal translucency measurement between 11 and 14 gestation's week by ultrasonographic screening is considered a marker for aneuploidies. The presence of a thickened nuchal translucency, even if the karyotype result is normal, can be associated with structural abnormalities (congenital heart diseases) (**Fig. 15**).

In other cases, the ultrasound study permits us to confirm fetal pathologies such as anencephaly (absence of a portion of the brain and skull) or omphalocele (abdominal wall defect in which the intestines and occasionally other organs remain outside of the abdomen) (**Fig. 16**).

Fig. 14 Different three-dimensional echographic modes. These allow us to assess the morphology, volumetry and vascularization of the structures studied.

Fig. 15 Prenatal diagnosis. The use of ultrasound in prenatal diagnosis allows us to screen the fetal pathology at week 12.

Fig. 16 Diagnosis of malformative fetal pathology by ultrasound.

Ectopic pregnancy (implantation of gestation outside the endometrial cavity) remains the most important cause of first trimester maternal death. Traditionally, laparoscopy has been the gold standard for its diagnosis. The advent of high-resolution transvaginal scan provides an earlier diagnosis, well before surgery becomes necessary. Early diagnosis by transvaginal ultrasound is therefore potentially lifesaving and can reduce surgical morbidity by allowing elective surgery or even non-surgical conservative treatment options.

The diagnosis of ectopic pregnancy combining the ultrasonographic studies and the determination of the levels of hCG is vital for its early diagnosis. In view of the suspicion of a complicated ectopic gestation (bleeding inside the abdominal cavity), we must perform a laparoscopy that will confirm the diagnosis and accomplish an appropriate treatment (removing the ectopic gestation) (Fig. 17).

Fig. 17 Ectopic pregnancy is today the leading cause of maternal mortality during pregnancy. Its early diagnosis is mandatory to avoid complications as serious as the death of a pregnant woman.

Glossary

Aneuploidy Any deviation from an euploid chromosomal constitution due to the presence of either fewer or more chromosomes.

Chromosomal mosaicism Presence within the same embryo of cells with different karyotypes due to an error in chromosome segregation occurring during the mitotic divisions postfertilization. Both aneuploid mosaicism (different aneuploid cell lines) or euploid/aneuploid mosaicism (mix of euploid and aneuploid cell lines) are possible.

Euploidy The presence of a normal karyotype within a cell. In humans, a correct karyotype is $2n$ (46 chromosomes), where n is the haploid number of chromosomes.

Full chromosome aneuploidy Chromosomal imbalance that involves the whole sequence of a chromosome. Full chromosome aneuploidy can be either a monosomy or a trisomy.

Ploidy Number of sets of chromosomes within a cell. Haploid ($1n$), diploid ($2n$), triploid ($3n$), tetraploid ($4n$), etc.

Preimplantation genetic testing for aneuploidies (PGT-A) Diagnostic methodology that allows comprehensive testing for the presence of aneuploidies using molecular techniques in a biopsy sample retrieved from a human embryo.

Prenatal diagnosis (PND) Diagnostic methodology that allows comprehensive testing for the presence of aneuploidies and/or monogenic disorders using molecular or cytogenetic techniques in a fetus-derived specimen collected via amniocentesis or chronic villi sampling.

Segmental (or partial) aneuploidy Chromosomal imbalance that involves only a portion of a chromosome. Segmental aneuploidies include deletions or duplications.

Structural aneuploidy Karyotypic imbalance that involves the rearrangement of large regions of a chromosome and that occurs within it or between other chromosomes (i.e., inversions, translocations, either robertsonian, which involve acrocentric chromosomes, or reciprocal, which involve any other chromosome).

Targeted amplification DNA amplification strategy directed to specific DNA sequences of interest in the genome.

Technical artifact Chromosomal or genetic imbalance observed in a scientific investigation that is not naturally present, but occurs because of the preparative or investigative procedure (i.e., preferential amplification, allele drop-in, allele drop-out, etc.).

Whole genome amplification (WGA) Random DNA amplification strategy aimed at increasing the starting DNA template, typically from a single or few cells. By amplifying 40%–60% of the whole genome, this strategy allows the generation of a quantity of DNA sufficient to perform downstream molecular analyses.

Preface

In the preimplantation and prenatal periods, chromosomal abnormalities include a wide range of genomic imbalances, from polyploidy, whole chromosome and large structural aneuploidies, down to submicroscopic deletions and duplications. Whilst the impact of some karyotypic abnormalities on embryo and fetal development and associated reproductive outcomes are well-defined, the downstream consequences of many other smaller imbalances are still largely unknown.

This article is structured as an overview of the most prevalent chromosomal abnormalities and their impact on human reproduction. Furthermore, we will focus on preimplantation genetic testing for aneuploidies (PGT-A) as the most recent valuable tool to avoid the transfer of aneuploid embryos during IVF treatments, and review novel findings from basic research that reveal future possibilities for minimizing the occurrence of chromosome segregation errors.

Main Classes of Chromosomal Imbalances in Humans

Whole Chromosome Aneuploidies

Whole chromosome aneuploidies are defined as monosomies and trisomies for entire chromosomes, and undoubtedly represent the single most important cause for implantation failure and miscarriage (> 50% of sporadic first trimester pregnancy losses) in humans (Hassold and Hunt, 2001). Also, they have been extensively investigated due to their clear association with chromosomal syndromes and intellectual disability (Hassold and Hunt, 2001). The overall incidence of chromosomally abnormal pregnancies is highly dependent on female age and it is reported to be as high as 4% in stillbirths and about 0.3% in newborns (Hassold and Hunt, 2001) (Fig. 1). In fact, as women age from menarche to menopause, their oocytes become increasingly susceptible to chromosome segregation errors during the meiotic process. Extensive analysis of the main autosomal trisomies in clinical pregnancies revealed that > 90% had a meiotic origin. Most of the aneuploidies in embryos are due to chromosomal segregation errors occurring in the oocyte, with > 75% due to errors in meiosis I and < 25% due to errors in meiosis II, whilst current estimates suggest that a minority (1%–2%) of the spermatozoa are chromosomally impaired (Hassold and Hunt, 2001). Similarly, at the blastocyst stage, most of the

Fig. 1 Incidence of whole chromosome aneuploidies, microdeletions and microduplications (MMs), euploid/aneuploid mosaicism, ploidy imbalance and UniParental Disomy (UPD) across pre-/postimplantation developmental stages: oocyte, embryo, Product of Conception (POC), ongoing pregnancy and newborn. ND, Not detected/detectable; VOUS, Variants of unknown significance. Ranges are shown as full color (=minimum value) and faint color (=maximum value).

aneuploidies were classified as meiotic. The age-related processes that lead to the exponential increase in aneuploid conceptions are increasingly understood and novel insights into the molecular mechanisms of chromosome segregation during female meiosis are being explored (Ottolini et al., 2015). Because there are no therapies available to counteract the age-related increase of aneuploidies, diagnostic programs worldwide, either on preimplantation embryos during IVF cycles or in the prenatal period (prenatal diagnosis, PND), were established to detect the presence of an aneuploid conception, especially for women of advanced reproductive age. At present, the only interventions available to minimize the occurrence of an aneuploid pregnancy are: (i) fertility preservation through oocyte vitrification in young women, or (ii) PGT-A at the blastocyst stage during IVF treatments. Indeed, PGT-A is indicated for those couples with recurrent pregnancy loss (RPL), advanced maternal age (AMA), or recurrent implantation failure (RIF) in previous IVF cycles, to improve the embryo selection process by preventing the transfer of an aneuploidy embryo and reduce the chance of implantation failure and miscarriage (Dahdouh et al., 2015; Chen et al., 2015).

When assessed in embryos at different preimplantation developmental stages, monosomies and trisomies are observed at equivalent rates (Capalbo et al., 2014). On the contrary, population studies of newborns and miscarried products of conception, suggest that all monosomies, except for those involving the X chromosome, are incompatible with late embryonic development and early fetal life. However, although some autosomal trisomies and sex chromosome abnormalities are permissive of implantation, most of them result in developmental arrest within the first 12 weeks of gestation (Fig. 1).

Nearly 40% of human preimplantation embryos arrest around day 3–4, when they reach 8-cell/morula stage and compaction normally occurs. A portion of these embryos contains fragmented cells, suggestive of error-prone cleavage divisions associated with DNA damage. Some data suggest that aneuploidies and associated haploinsufficiency of dosage-sensitive genes are involved in preimplantation embryo arrest (Vega et al., 2014). However, clear evidence of how these mechanisms may cause mitotic arrest in preimplantation embryos is still missing, and other datasets are in favor of an opposite view. Specifically, when human blastocysts are assessed in PGT-A cycles, all range and spectra of aneuploidies are detected, including complex aneuploidies (Figs. 1 and 2). Thus, meiotic aneuploidies do not appear to be selected against during preimplantation development and do not cause major differences neither in the morphological quality nor in the morphokinetic behavior of developing human blastocysts (Capalbo et al., 2014; Rienzi et al., 2015). Notably, although aneuploidy rate in IVF blastocysts produced by women older than 44 reaches > 90%, around 30% of embryos produced by young women are aneuploid (Franasiak et al., 2014) (Figs. 1 and 2). Moreover, blastocysts show a chromosome-specific susceptibility to chromosome segregation errors associated with increased maternal age (Fig. 2). Specifically, larger chromosomes show an overall lower risk of errors and do not show a significant increase in their risk of aneuploidy with advanced female age. In general, the smaller the chromosomes (for instance chromosomes 21 and 22), the higher their susceptibility to the maternal age effect. On the other hand, sex chromosome showed a very low aneuploidy rate (2.3% of all the aneuploidies detected; Fig. 2), and their risk appears to be independent from female age as these abnormalities are generally related to defective segregation during spermatogenesis. Whole chromosome aneuploidies are very well understood and their impact in reproduction has been well defined in the last decades of genetic investigations. Diagnostic programs either at the preimplantation or prenatal stage can be effectively performed and accurate genetic counseling can be provided to couples when an abnormality is detected.

Fig. 2 Incidence of whole-chromosome aneuploidies in human blastocysts per woman age at egg retrieval (A), and prevalence of chromosome-specific monosomies and trisomies among all the aneuploidies detected (B). The figure reports the data produced in >5000 blastocysts tested at GENETYX (years 2013–2016) through a qPCR-based 24-chromosome aneuploidy testing technology (described by Treff et al., 2012).

Chromosomal Mosaicism

Whole chromosome aneuploidies are defined as constitutive when the error occurs along gametogenesis because of defective segregations during meiosis, with the ensuing embryo showing the extra/missing chromosome/sequence. Nonetheless, postzygotic errors in chromosome segregation may also occur and cause aneuploidies. Aberrant mitotic segregations occurring during initial cleavage divisions result in chromosomal mosaicism, a phenomenon that involves the presence of cell lines with different karyotypes within the same embryo. Detection frequency of euploid/aneuploid mosaic blastocysts differs across IVF centers and diagnostic laboratories and represent the main biological source of a potential diagnostic inconsistency in preimplantation/prenatal genetics. For this reason, the incidence and prevalence of chromosomal mosaicism in human blastocysts is a topic at the center of current investigation and debate. The most recent data suggest that about 5% of human blastocysts may show this constitution (Fig. 1), as collectively reported by at least four studies (reviewed in Capalbo et al., 2016) that analyzed the inner cell mass (ICM) and 2–3 fragments of trophoctoderm (TE) from > 100 disaggregated blastocysts donated for research. Due to the absence of appropriate checkpoints at early cleavage stages, it is likely that human embryos do not experience strong negative selection of cells bearing aneuploidy, chromosome breakage or segmental aberrations (Kiessling, 2010). Consequently, these abnormal cells are included in the developing embryo, causing genetic mosaicism to persist beyond early developmental stages without affecting cellular differentiation in a ploidy-dependent fashion. Moreover, in murine mosaic embryo models no evidence has been found for preferential allocation of aneuploid cells to embryonic or extra-embryonic lineages (Bolton et al., 2016). In agreement with these findings, it has not been found any sign for preferential allocation of abnormal cells towards one or the other cell lineage in mosaic human blastocysts (Capalbo et al., 2013). Indeed, abnormal cells in euploid/aneuploid mosaic embryos are evenly distributed across different blastocyst sections, including ICM only. Lastly, the “self-correction” model suggesting that abnormal chromosomes are fixed to a normal disomic configuration by a second mitotic error event correcting the original one is not supported by recent findings showing very low incidence of uniparental disomy (UPD) at the blastocysts stage (Gueye et al., 2014) (Fig. 1). In a PND study involving > 5300 fetuses, the rate of mosaicism in humans did not exceed 1.32% in either spontaneous or IVF-derived pregnancies as reported by Huang and colleagues (Huang et al., 2009). Such rate is in line with the 5% reported at the blastocysts stage. In the same study, the authors also outlined that true fetal mosaicism (not only confined to the placenta) has an even lower prevalence: 0.3%–0.44% (Fig. 1). These data are sufficient to define the prevalence of mitotic errors in human reproduction as relatively limited.

Whilst meiotic aneuploidies are uniformly present in all cells and can be accurately detected and managed in clinical diagnostic programs (Hassold and Hunt, 2001), the embryonic fate and the clinical consequences of mosaic aneuploidies may depend on several variables. These include which chromosome is involved in the aneuploidy, when the error occurred during preimplantation development, what proportion of the embryo is aneuploid, and where the abnormal cells are located within the embryo (Capalbo and Rienzi, 2017). Therefore, the clinical implication of a mosaic aneuploidy can be described as unique for each event and difficult to decipher in the absence of well-defined genotype/phenotype associations. Issues related to segregation and spatial allocations of aneuploid cells in a mosaic preimplantation embryo have recently raised concerns about the applicability and the effectiveness of PGT-A programs. It is widely accepted that, for blastocyst stage embryos, 5–10 randomly selected TE cells can be analyzed to infer the chromosomal configuration of the ICM. Indeed, the diagnosis of genetic imbalances in preimplantation embryos by taking a small TE biopsy does not represent a limitation for uniform aneuploidies. However, when dealing with mosaic euploid/aneuploid embryos, the biopsied TE cells might not be representative of the actual chromosomal constitution of the ICM, potentially causing misdiagnosis of the embryonic karyotype (Capalbo and Rienzi, 2017). Moreover, inherent technical limitations of comprehensive chromosome testing (CCT) technologies for assessment of mosaicism in a multicellular TE biopsy, persist. Presently, the identification of a condition compatible with mosaicism is based on bioinformatics tools, which, in the absence of specific diagnostic approaches, may result in the misinterpretation of an intermediate chromosome copy number falling in between the disomy and the aneuploidy thresholds (intermediate log 2 ratio or copy number value). None of the CCT methods has clinically standardized criteria to unequivocally distinguish between technical variation and genuine mosaicism (Capalbo et al., 2016). Indeed, the fluctuations of copy number profiles can be explained by a multitude of different technical and biological factors (reviewed in Capalbo and Rienzi, 2017). Both functional and prospective nonselection studies aimed at modeling the clinical fate and the reproductive potential of human embryos with an intermediate copy number profile are lacking. Therefore, until a more comprehensive diagnostic strategy is developed, mosaicism should be recognized as a biological limitation for PGT-A programs, as it is also for PND. Indeed, it is still reasonable to avoid reporting mosaicism in PGT-A cycles until its impact on clinical treatment is clarified. Alternatively, genetic reports could include the option of “analysis showing patterns consistent with mosaicism”, in which case patients should undergo extensive genetic counseling prior to transferring the embryo.

Structural and Segmental Chromosome Aneuploidies

Constitutive structural chromosome abnormalities

The most common structural chromosome abnormalities are balanced reciprocal translocations with an incidence in PND of 1 out of 560 fetuses, and balanced Robertsonian translocations and inversions with an incidence of 1 out of 1100–1200 fetuses. Instead, the incidence of unbalanced structural abnormalities is even lower (Franssen et al., 2005). However, a history of recurrent miscarriages in young women suggests an increased risk of structural chromosome abnormality in one of the partners (Franssen et al., 2005). To this regard, the incidence of balanced structural chromosome abnormalities is 0.7% in the general population and increases to 2.2% after one miscarriage, 4.8% after two miscarriages and to 5.2% after three miscarriages (De Braekeleer and Dao, 1990).

Structural chromosomal abnormalities in one of the partners may result in the production of chromosomally unbalanced gametes that cause meiotic impairment and, in general, infertility. Implantation failure, early or late miscarriage, or an ongoing pregnancy resulting in physical and/or mental disabilities in the child are the range of possible consequences underlying the production of an unbalanced embryos. Yet, recurrent miscarriage is more common when the abnormality is present in the maternal karyotype rather than in paternal one. This is due to sex-specific differences in the meiotic silencing checkpoint, which normally eliminates chromosomes that are not perfectly paired in spermatogenesis, thus the meiotic silencing checkpoint is not as stringent in mammalian oocytes compared to sperm. Moreover, structural impairments would commonly result in low fertility, especially in males, as highlighted in cytogenetic studies of gametes from patients with balanced structural chromosome abnormalities (Kurahashi et al., 2012).

Once a structural chromosome abnormality has been revealed in one of the partners, either prenatal chromosomal analysis or preimplantation genetic testing for chromosome structural imbalances during an IVF treatment can be performed to identify normal (balanced) and abnormal (imbalanced) conceptuses.

De novo segmental chromosome aneuploidies

Segmental aneuploidies, such as chromosome deletions and duplications, are major contributors to genomic variability. Although some of them do not affect cellular physiology, a subset of them is pathogenic. Their origins are equally distributed between maternal and paternal chromosomes and female age does not appear to affect their incidence.

Partial aneuploidies (a class of copy number variations, CNVs) can be either inherited or arise because of a de novo event. The former possibility is rather infrequent and occurs in <1% of miscarriages; more often, they originate as an error in the male or female meiosis, apparently at similar rates (Ottolini et al., 2016). The estimated prevalence of chromosomal deletions in the neonatal population ranges from 0.5–2 per 10,000 births (Vega et al., 2014). A recent study reported that $\approx$ 5% of all chromosome abnormalities are deletions, including microdeletions, giving a prevalence of 1.99 per 10,000 births. Duplications are even less common, showing a prevalence of 0.7 per 10,000 births and representing $\approx$ 2% of all the chromosome abnormalities identified (Wellesley et al., 2012). Although CNVs are less frequent than full chromosome aneuploidies, their impact on embryo development may be equally dramatic if they alter the copy number state of putative dosage-sensitive genes.

Among CNVs types, large deletions and duplications are rare events, while chromosomal microdeletions and microduplications (MMs), which involve sequences generally smaller than 5 Mb, make up the most significant fraction of subchromosomal CNVs and a class of them have been clearly defined as pathogenic. These types of recurrent CNVs are classified as genomic disorders and their underlying molecular mechanisms and phenotypes are the best-characterized imbalances in the genome. In the last decade, > 200 recurrent MM syndromes with developmental delay and intellectual disability have been identified. In large prenatal investigations, pathogenic MMs, have been reported with an incidence of about 0.5% in pregnancies and without any identified female age effect (Wapner et al., 2012) (Fig. 1).

As novel technologies have progressively improved the detection of smaller CNVs across the genome, many studies over the last decade suggested a growing spectrum of size and phenotypic effects of CNVs, ranging from adaptive traits to full diseases, as well as embryonic lethality.

While their prevalence in pregnancies and newborns is relatively low, their estimates and pathogenicity in preimplantation embryos are poorly defined. This limited knowledge is a consequence of the paucity of DNA retrieved from the few trophoctoderm cells composing a blastocyst biopsy. Specifically, a whole genome amplification (WGA)-based DNA amplification step is required, which may impact the reliability of the diagnosis. Indeed, current technologies do not cover the genome evenly but just a portion of it (40%–60%), thus limiting genome resolution and MMs detection (Cawad et al., 2016), because of occasional introduction of amplification bias (Capalbo et al., 2015). Moreover, it is noteworthy that a repository database of CNVs and their developmental outcomes for preimplantation embryos is still lacking. The absence of such knowledge makes it complex to give a clinical interpretation of the reproductive impact of the CNVs detected in the preimplantation period.

Preimplantation Genetic Testing for Aneuploidies

The reproductive competence of an embryo is unavoidably dependent on its intrinsic capability to implant. This potential cannot be improved with any of the IVF clinical strategies used, but possibly only predicted through embryo selection tools that, when applied, should not impact the embryo itself. To date, PGT-A has proven to be the only valuable IVF approach to limit the impact of aneuploidies on human reproduction. Indeed, by identifying aneuploid embryos in a cohort produced by a couple during an IVF cycle, and by allowing to transfer euploid embryos, PGT-A does improve the efficiency of ART (increased implantation rate per transfer, reduced miscarriage rate and time-to-pregnancy, etc.), possibly with no impact on its efficacy (i.e., the number of babies born per cycle). Based on the current knowledge, the best PGT-A strategy involves comprehensive chromosome testing (by array single nucleotide polymorphisms, array comparative genomic hybridization, quantitative polymerase chain reaction and, more recently, next generation sequencing) of a trophoctoderm biopsy retrieved at the blastocyst stage. This is a strategy that (i) guarantees the most reliable information about embryonic karyotype (including male-derived aneuploidies and clinically-relevant mitotic errors); (ii) does not impact embryonic intrinsic developmental potential as shown in a paired randomized controlled trial (RCT) (Scott et al., 2013; Cimadomo et al., 2016); (iii) is cost-effective, since only developmentally competent embryos, that developed to the blastocysts stage, are analyzed; (iv) shows high positive ($\geq$ 50%, independently from female age at oocyte retrieval) and

negative ($\geq 96\%$) clinical predictive values as reported in a prospective nonselection RCT (Scott et al., 2012); and (v) is clinically effective, as shown in all the RCTs and observational studies recently reviewed in two meta-analyses (Dahdouh et al., 2015; Chen et al., 2015).

Novel Basic Research Findings

Despite PGT-A being an efficient diagnostic tool, it does not modify the genetic status of the oocytes/blastocysts generated during an IVF cycle. When a woman no longer produces chromosomally normal oocytes/embryos, PGT-A is ineffective in terms of IVF outcomes. Indeed, basic research avantgardes in this field aim at identifying novel strategies to operate onto oocytes/embryos, and to eventually reduce their aneuploidy risk and improve their reproductive competence.

First, unraveling what other factors (beyond woman aging) cause aneuploidies may provide the community with lifestyle guidelines to minimize the incidence of miscarriage, and try to extend female reproductive lifespan. Furthermore, beyond precautionary measures, we may also attempt to target cellular processes involved in aberrant chromosome segregation, and prevent (or rectify) their occurrence. For instance, Wu and colleagues are administering salubrinal to obese mice to counteract metabolic stress in the endoplasmic reticulum triggered by the diet, thus restoring the oocyte maturation potential both in vivo and in vitro (Wu et al., 2015).

Second, the complete characterization of the meiotic machinery, of its individual components function and of upstream regulators may reveal key gene/protein targets whose function must be preserved to guarantee a correct meiosis (e.g., DNA damage response genes). With this knowledge, it will be possible to design novel IVF protocols where immature oocytes are collected before meiotic completion and let them progress through the meiosis process in vitro with the support of stabilizing agents and molecules.

Third, chromosome therapy is a fascinating perspective to perform functional correction on living cells. To date, two main strategies have been tested in human/animal models and published: the *XIST* (*X-inactive specific transcript*)-driven heterochromatization of chromosome 21 to conduct dosage compensation in induced pluripotent stem cells from a Down syndrome individual (Jiang et al., 2013); the *ZSCAN4* (*zinc finger and SCAN domain containing 4*) mRNA-mediated correction of trisomy 18 and 21 to a correct chromosome number in human cell cultures and murine embryonic stem cells (Amano et al., 2015).

Last, mRNAs or inhibitors may be adopted to sustain in vitro maturation or embryo development by preserving genetic integrity.

Although these are only putative desirable perspectives at present, future technologies may be able to counteract the natural mechanism of reproductive aging and ultimately increase the cumulative live birth rate per started cycle in IVF.

Conclusion

Human reproduction is highly dependent upon a correct chromosomal constitution, which is especially reliant on a correct female meiosis. Indeed, maternal age and embryo reproductive competence are closely connected. The possibility of developmental progression in presence of meiotic errors throughout, but mainly beyond, the preimplantation period is limited to few trisomies (e.g., 13, 18, and 21), some segmental and sex chromosomes aneuploidies, especially in presence of low-grade chromosomal mosaicism. Nevertheless, the understanding of human preimplantation development is limited due to ethical and legal restrictions on embryo research and scarcity of material, and currently the only valuable clinical tool to limit the incidence of aneuploidies in humans is PGT-A. Additionally, studies in humans are mainly descriptive and lack functional evidence. Most of the information on embryo development is obtained from animal models and embryonic stem cell (ESC) cultures; hence any conclusion or generalization should be extrapolated with caution. Nonetheless, novel imaging and genetic technologies now provide the tools to further investigate these mechanisms with more accuracy and precision. It is therefore expected that upcoming studies combining genetic, embryology and developmental biology data will be able to answer some of these fundamental biological questions in the near future.

Glossary

Colpomicrohysteroscope An endoscopic visualization instrument, which unlike other optics, has a magnification capability of up to 40 ×.

Reproductive unit The ovaries, fallopian tubes, and uterus constitute a group of organs that work together to perform a specific function: reproduction.

Abbreviations

ATPF Altered tuboperitoneal factor

HSG Hysterosalpingography

PID Pelvic inflammatory disease

To facilitate understanding, we will define “reproductive unit” as the group of sexual organs inside the female pelvis, each of which performs a specific and irreplaceable function:

- The ovary produces oocytes.
- The fallopian tube transports both gametes, is where fertilization takes place, nourishes the early embryo, and delivers the embryo to the uterus.
- The uterus is the place where the embryo develops until it is ready to be delivered.

This reproductive unit is in close proximity to a number of abdominal-pelvic organs, the closest of which are the bowel and the bladder, and it is also associated with the peritoneal serosa.

The extraperitoneal location of the ovary does not protect it from pathological events occurring in the pelvic peritoneum and that affect the proper functioning of the gonad.

The fallopian tube is not a mere tube that transports cells, but is rather an active organ that plays a crucial role in the reproductive process.

Different pathogens can easily reach the peritoneal cavity and damage the reproduction unit, the abdominal organs, and the peritoneum.

The tuboperitoneal factor is the relationship among the ovaries, fallopian tubes and uterus, and between these reproductive organs and the non-reproductive abdominal organs and the peritoneum.

The tuboperitoneal factor can be affected by several events:

- Adnexal infections (salpingitis, adnexitis, etc.)
- Pelvic infections (pelvic inflammatory disease, PID)
- Degenerative processes, such as endometriosis
- Mechanical factors associated with contraceptive procedures (tube ligation) or with inadequate surgical procedures that damage the surface of the peritoneum or integrity of the organs, especially the adnexae

Tubal factor pathology can present with different manifestations:

- (a) *Adhesions*: Adhesions are pathological bonds that form between organs. They can vary in structure, thickness, and size, and can be vascular or avascular, thick or filmy, and involve only a part or the entire surface of the ovaries and tubes, isolating them or binding them together, to other pelvic organs, and/or to the peritoneum. These adhesions result in altered tuboperitoneal factor (ATPF) (Figs. 1–3).

The causes of ATPF include pelvic inflammatory disease (PID), endometriosis, malformations, and pelvic surgery sequelae affecting the uterus, adnexae, and/or organs in close proximity to the genital system as a result of iatrogenic surgical procedures (appendectomy).

- (b) *Damaged tubal patency caused by obstruction*: Tubal disease can be partial (obstruction) or total (occlusion), and can involve the proximal, medial, or distal portion of the tube.

Proximal tubal obstruction is the blockage of the oviduct at the level of the cornua of the uterus, and is rarely partial (Fig. 4).

Medial tubal occlusion affects the isthmic portion of the fallopian tube and results from mechanical factors, such as voluntary tubal ligation and iatrogenic surgical procedures, as well as infectious degenerative diseases (Fig. 5).

Fig. 1 Filmy adhesions from the ovary to the peritoneum.

Fig. 2 Dense adhesions between the ovary, the tube, bowel, and uterus.

Fig. 3 Severe affected tubo-peritoneal factor.

Fig. 4 Hysterosalpingography. Proximal tubal obstruction. The dye has not spilled into the tubes.

Fig. 5 Medial tubal obstruction.

Distal tubal obstruction involves the fimbrial end of the tube, and is caused by damage to the tubal serosa. It can present as:
Phimosis: (a) prefimbrial: prefimbrial phimosis is a ring-like fibrous narrowing at the ampullary-fimbrial junction; (b) post-fimbrial: postfimbrial phimosis is an adherence that covers all the fimbriae, distorting their typical finger-like appearance. Patency is maintained in both prefimbrial and post fimbrial phimosis.

Fimbrial conglutination: The distal end of the fallopian tube is completely occluded, but with no distention of the lumen.

Hydrosalpinx: It is the most severe form of tubal damage. The tube is distally occluded and dilated. The integrity of the salpingeal epithelium is severely affected (**Figs. 6 and 7**).

(c) *Both pathologies combined*. This is the most frequent case. Tubal damage is usually accompanied by peritoneal adhesions.

Fig. 6 Hysterosalpingography. Bilateral hydrosalpinx.

Diagnostic Methods

Tuboperitoneal factor evaluation means making sure all the pelvic structures are in the right place, in proper relationship to one another, and capable of functioning.

Assessment of tuboperitoneal factor can be performed using hysterosalpingography, hysterosonography, laparoscopy, and salpingoscopy.

Hysterosalpingography (HSG) is a radiographic study that has been used for almost 100 years. Nevertheless, it has not lost validity and is widely used. The method consists of instilling a water-soluble iodinated solution into the uterus through the cervix, using a special cannula. The solution must be injected slowly and progressively to avoid masking surface lesions of the uterus cavity and causing pain to the patient. The procedure is performed while using fluoroscopy with intermittent still images for documentation.

The obtained images allow visualizing the shape of the cervix, isthmus, uterus cavity, tube patency, and the passage of the contrast dye into the abdominal cavity (Fig. 8).

Fig. 8 Normal hysterosalpingography. Note progressive filling of the uterus, both tubes, and passage of the dye into the abdominal cavity.

This method is not useful for diagnosing peritoneal adhesions except for very severe cases involving the distal end of the tube, in which case the images will show peritoneal sacs filled with the contrast dye. These images are often confused with hydrosalpinx (Figs. 6 and 9).

Hysterosonography is a useful method that can be employed in the office setting. It merely involves instilling saline solution through the cervix using a cannula similar to that used for HSG, and then observing the passage of the solution in the abdominal cavity using the transvaginal ultrasound transducer. It is very useful to examine the uterus. Its high resolution not only allows examining the contour of the uterus but also the structure of the uterine wall, thus providing a complete evaluation of the organ. Conversely, it is not recommended for observation of the tubes; the resolution quality of the images of the contour of the salpinx walls and the resolution of the details of the tubal folds is inferior to that of HSG. This method only provides information on the passage of liquid in the pelvic cavity, and is therefore not considered the method of choice by most physicians.

Laparoscopy is the choice method for diagnosing pelvic adhesions; the latter cannot be detected by ultrasound or by radiographic studies. Although it is a surgical procedure, which must be performed under general anesthesia in an operating room, the advent of small caliber laparoscopes, 5 mm in diameter, allows carrying out the procedure on an outpatient basis. It poses the additional advantage of being therapeutic, since pathology can be treated upon detection without affecting the post-operative course of the patient (Figs. 10 and 11).

Salpingoscopy is the micro endoscopic examination of the tubal mucosa. It is performed as follows: (Marconi et al., 1992) during laparoscopy, methylene blue diluted in 10% saline solution is injected through the cervix to stain damaged mucosa cells. Saline solution is instilled immediately after in order to rinse the stain and dilate the tube, and thus facilitate endoscopic visualization. Examination is performed using a colpomicrohysteroscope without an irrigation sheath, inserted in the abdominal cavity through the second laparoscopic trocar, to then canalize the tubal ostium. An advantage of colpomicrohysteroscopy over other types of optics is that the magnification device it employs allows microscopically examining details of the tubal mucosa. The parameters typically analyzed by salpingoscopy include: (a) the appearance of the endosalpingeal folds (Figs. 12–14) (b) the vessels, (c) the presence of adhesions in the tubal lumen (Fig. 15), and (d) the presence of methylene-blue stained cell nuclei in the endosalpinx (Fig. 16). The presence of adhesions in the tubal mucosal folds or blocking the lumen, in addition to the finding of methylene-blue

Fig. 16 Salpingeal mucosal folds showing a great number of stained cell nuclei.

stained cell nuclei are indicators of bad prognosis and irreversible damage seriously affecting tube recovery (Video 1 in the online version at <https://doi.org/10.1016/B978-0-12-801238-3.64728-1>). A number of authors have proposed salpingoscopy as a routine procedure to assess tubal factor (Marconi et al., 1992; De Bruyne et al., 1997; De Bruyne et al., 1989; Marana et al., 1995; Heylen et al., 1995; Shapiro et al., 1988).

Conclusion

As stated at the beginning of this chapter, the key to treatment success is precise and accurate diagnosis.

The diagnostic battery for diagnosis of tuboperitoneal factor includes hysterosalpingography, hysterosonography, laparoscopy, and salpingoscopy. Clearly, it is not mandatory to perform all these tests to rule out tubal pathology. Nevertheless, it can be stated that, like hysterosonography, hysterosalpingography is the method of choice to confirm fallopian tube patency and uterine cavity integrity. The latter can also be confirmed by hysterosonography. Aside from very rare exceptions, without laparoscopy it would be impossible to confirm that the patient has no adnexal-peritoneal adhesions. Salpingoscopy is the real gold standard to evaluate the integrity of the tubal mucosa.

Glossary

16S rRNA Is the component of the 30S small subunit of a prokaryotic ribosome. The 16S rRNA gene sequencing is used for phylogenetic studies, as its presence is highly conserved among bacteria, but its sequence has diverged across evolution becoming species-specific.

Biofilm An assemblage of surface-associated microbial cells that is enclosed in an extracellular polymeric matrix. Biofilms can be formed by a single bacterium, but are often made up of several species of bacteria, as well as fungi, algae, and protozoa.

Community state types (CST) Profile that defines the total bacterial community of a given body site based on the relative abundances of each bacteria.

Dysbiosis Is defined as a shift in the physiologic microbiota resulting in an imbalance between commensal and pathogenic bacteria. It is speculated that changes in microbial composition contributing to the initiation and/or persistence of many diseases.

Endometrial receptivity analysis (ERA) Is a personalized genetic test, developed and patented in 2009 by IGENOMIX, to diagnose the endometrial receptivity state in the window of implantation.

Human microbiome project (HMP) Initiative launched by the National Institutes of Health (USA) with the goal of identifying and characterizing the microorganisms that are found in association with the human body. This project aimed to test how changes in the human microbiome are associated with human health or disease.

Metagenomics Use of DNA sequencing techniques to study DNA extracted directly from environmental samples, which gives the whole profile of the microbial diversity within the sample, avoiding limitations of traditional microbiological culture. In addition to the information about taxonomic diversity, metagenomics can provide insights into the physiology of the organisms present in the environment.

Microbiome The totality of microorganisms and their collective genetic material present in or on the human body.

Next-generation-sequencing (NGS) Modern technologies that allow the sequencing of DNA and RNA much more quickly and cheaply than the previously used Sanger sequencing, revolutionizing the study of genomics and molecular biology.

Operational taxonomic unit (OTU) Is a term used to classify groups of closely related individuals. This concept is generally used to refer to clusters of organisms, grouped by DNA sequence similarity of a specific taxonomic marker gene. OTUs are the most commonly used units of microbial diversity, especially when analyzing 16S rRNA gene.

The Human Microbiome

The concept of the human microbiome was suggested in 2001 by Joshua Lederberg who defined it as “the ecological community of commensal, symbiotic, and pathogenic microorganisms that literally share our body space” (NIH HMP Working Group, 2009). This community includes microorganisms as eukaryotes, archaea, bacteria and viruses, wherein bacteria are the most numerous, and better studied members of the human microbiome.

These microbes are not generally harmful for us; in fact, when these commensal bacteria are in balance, they play fundamental roles in human health. For example, they produce some essential vitamins that the human body is not able to produce on its own, break down our food to obtain nutrients, support the function of the immune system and even produce helpful anti-inflammatory compounds which interfere with other disease-causing microbes. In contrast, it has been seen that changes in the microbiome composition or an imbalance of the microbial communities are correlated with numerous pathologies such as asthma, atopic dermatitis, periodontal disease, obesity, cancer, Crohn’s disease and other gut alterations (Dietert and Dietert, 2015).

Most published medical literature has focused on the microbiome involved in pathogenesis, while only few publications have focused on the physiologic role that the microbiome plays. The importance of this physiologic role was evidenced in 2007 by the Human Microbiome Project (HMP), led by the National Institutes of Health (NIH), that characterized the microbiome of different body sites in healthy volunteers in order to understand the synergistic interactions between the microbiome and its host. This project provided novel and valuable data through the comprehensive analysis of global communities, and raised the possibility of improving human health through monitoring or manipulating the human microbiome (NIH HMP Working Group, 2009).

Characterization of the Human Microbiome

Much of our knowledge about the human microbiota comes from culture-based approaches. Nevertheless, many organisms cannot be identified with this technique. Depending on the body site, it has been estimated that between 20% and 60% of the human microbiome is uncultivable (NIH HMP Working Group, 2009), which results in underestimation of the ecosystem diversity as well as failing to identify microorganisms associated with a disease. For this reason, although the culture data are still informative and useful, must be reinterpreted within the new technological scenario.

Uncultivable species are now detectable thanks to advances in genome sequencing. Metagenomic sequencing techniques have enabled researchers to look deeper into the microbiome and have revealed an enormous amount of information that was not previously accessible. Most published studies use the metagenomic sequencing technique of the 16S rRNA bacterial gene. This gene contains nine hypervariable regions (V1 to V9) placed among highly conserved sequences. These variable regions serve as a molecular fingerprint since they are species-specific, and the comparison of their sequences with annotated bacterial genomes allows for accurate and rapid assignment of the resulting operational taxonomic units (OTUs) with their microbial taxa. Although the microbial world was revolutionized by the analysis of the 16S rRNA gene, new techniques of whole genome sequencing (WGS) have provided another level of depth in bacterial identification as it has facilitated the study of the functional genes expressed by the microorganisms (Mor et al., 2015).

Another aspect that has helped the detection of uncultivable bacteria is the publication of known sequences, which have allowed a taxonomic classification based on DNA sequences of species. The Human Microbiome Project (“HMP,” www.hmpdacc.org) was launched in the United States by the National Institutes of Health to investigate and characterize the human microbiome in 250 healthy volunteers at multiple body sites (oral cavity, skin, respiratory, gastrointestinal and urogenital tract) (NIH HMP Working Group, 2009). A combination of 16S rRNA gene sequencing, metagenomic whole-genome sequencing (WGS), and bioinformatics were used to identify the composition of microorganisms in a particular sample and elucidate the functional complexity of the microbial community. This project focused on the establishment of standards for metagenomic studies and provided a quality database that served as the basis for future research on the human microbiome.

Microbiome of the Reproductive Tract

Bacteria that colonize the genital tract represent 9% of the total human microbiome (Sirota et al., 2014). It has been found that the microbiome of the genital tract is involved in the physiology and pathophysiology of reproduction, affecting from gametogenesis to fertilization, embryo migration and implantation. For example, alterations in this microbiome have been related with pregnancy loss and poor obstetric outcomes during gestation and delivery (Franasiak and Scott, 2015a).

Thanks to sequencing data of the gene coding for the 16S rRNA subunit, the microbiome of the male and female reproductive tract has begun to be characterized in order to understand the potential role in reproductive competence.

The female reproductive tract has long been known to have an active microbiome. Although the greatest focus has been on the vaginal microbiota, there are also studies that demonstrate that the remainder of the female reproductive tract is not sterile. Several studies to date have shown that there is a small but active microbiome in the uterine cavity. In this regard, a recent study has characterized the endometrial microbiome of reproductive age women and has demonstrated the existence of an endometrial microbiota that can differ from that on the vagina (Moreno et al., 2016). Some studies performed in different patient's populations have also found bacteria in the fallopian tubes of women without obvious tubal infectious pathology and there are additional studies that have shown that the ovaries present an indigenous microbiome, being the Firmicutes phylum and the *Lactobacillus* genus the most abundant microorganisms found throughout the female reproductive tract (Franasiak and Scott, 2015b; Miles et al., 2017) (Fig. 1). Moreover, other investigations have revealed that other organs involved in reproduction, such as the placenta, are colonized with their own unique microbiome (Aagaard et al., 2014).

The male reproductive tract has also been seen to have an active microbiome, even in men without evidence of acute or chronic inflammation of their reproductive tract. However, it is still unknown if an altered microbiome may harm the spermatozoa, or alternatively, if differences in the seminal content might create a milieu where different types of bacteria can survive (Franasiak and Scott, 2015b).

On the other hand, it is becoming evident that the microbiome is not only a simple accumulation of floating bacteria on the surface of a human tissue. In many cases, three-dimensional structures called biofilms are formed, which might inhibit immune detection and reduce the effectiveness of antimicrobial treatment. Biofilms are usually present in the vagina, but commonly extend into the endometrial cavity and even up on the fallopian tubes (Franasiak and Scott, 2015b). Although no definitive conclusions have been established regarding the role of biofilms in the reproductive tract, they could have an important impact on reproductive function. In this sense, their study may provide essential information to guide the development of new therapeutic interventions that could improve IVF procedures.

Vaginal Microbiome

In the past, most of the studies that characterized the microbiome of the reproductive tract analyzed vaginal samples, due to the previous belief that the uterine cavity was sterile. The HMP focused the study of the urogenital tract microbiome on the analysis of vaginal samples collected from three specific sites (introitus, midpoint and posterior fornix) obtained from 113 female subjects. The results of this study showed that vaginal tract has the lowest alpha (within-sample) and beta (between-samples) diversity values, compared to other body sites tested, meaning that this is a very stable microbiota (Franasiak and Scott, 2015b).

Fig. 1 Distribution of phyla by body site. Samples from each patient are grouped by individual body site. Each column represents the percent abundance of the indicated bacterial phyla present at each designated body site for an individual patient. Data for the five most common phyla are presented; all remaining phyla were grouped and classified as other. Reprinted from Miles, S. M., Hardy, B. L., and Merrell, D.S. (2017). Investigation of the microbiota of the reproductive tract in women undergoing a total hysterectomy and bilateral salpingo-oophorectomy. *Fertility and Sterility* 107(3), 813–820, Copyright 2017, with permission from Elsevier.

Fig. 2 Composition of vaginal microbiota in reproductive age women. The vaginal microbiota in healthy adult women can be divided into five community groups (CSTs). Group I, II, III, and V are dominated by *Lactobacillus* species belonging to *L. crispatus*, *L. gasseri*, *L. iners*, and *L. jensenii* respectively, while group IV can be separated into two subgroups—IV-A and IV-B. Community group IVA is characterized by the presence of a mixed population of *L. crispatus* or *L. iners* with strict anaerobes, while IVB has a higher proportion of anaerobes members. Reprinted from Petrova, M. I., Reid, G., Vaneechoutte, M., and Lebeer, S. (2017). *Lactobacillus iners*: Friend or foe? *Trends in microbiology*, **25**(3), 182–191, Copyright 2017, with permission from Elsevier.

It has been widely reported that the vaginal microbiota of healthy women is usually dominated by *Lactobacilli*, which represents between 90% and 95% of the total bacteria in the reproductive tract (Sirota et al., 2014). These bacteria play an important role in maintaining the vaginal health of women because they produce lactic acid, which lowers the vaginal pH, and some of them produce hydrogen peroxide (H_2O_2), bacteriocins and other antimicrobial substances to inhibit the growth of pathogenic organisms that might cause infections in the vagina (Sirota et al., 2014).

In a study carried out by Ravel et al. (2011), the vaginal microbiome of 396 women was analyzed using molecular techniques and subsequently classified into five community states types (CSTs) depending on their bacterial composition. More than 70% of women presented vaginal microbiota dominated by *L. crispatus*, *L. gasseri*, *L. iners* and *L. jensenii*, corresponding to CST–I, –II, –III and –V, respectively. Whereas a smaller proportion of women diagnosed of bacterial vaginosis (BV) exhibited a CST-IV vaginal microbiome, characterized by lower percentage of *Lactobacillus* spp. and higher levels of anaerobic bacteria such as *Aerococcus*, *Atopobium*, *Dialister*, *Gardnerella*, *Megaphaera*, *Prevotella* and *Sneathia*, among other genera (Fig. 2).

The vaginal microbiome may be influenced by factors including age, hygiene habits, sexual activity, pregnancy and exogenous hormones (Sirota et al., 2014). In addition, it has been observed that the vaginal microbiota differs among human races and geographical locations; Caucasian and Asian populations present a higher prevalence of *Lactobacillus* dominated microbiome in comparison with Hispanic and African American women who present a higher prevalence of a CST-IV microbiota (Ravel et al., 2011). Apart from the ethnicity, the vaginal microbiome may also be affected by hormonal changes over the course of the menstrual cycle. The intervals of high variability occur during menses, whereas the more stable intervals coincide with the higher levels of estradiol and progesterone during the late follicular and midluteal phases (Gajer et al., 2012).

Bacterial vaginosis

In healthy women, *Lactobacillus* are usually the dominant bacterial species in the vagina, but changes in the bacterial community composition (such as the growth of strict anaerobes and Gram-negative bacteria) may favor an imbalance in the physiological conditions of the urogenital tract, leading to dysbiosis or a pathological state. As a result, a common disorder called bacterial vaginosis (BV) may occur.

BV is the most common vaginal syndrome of reproductive-age women, whose prevalence in the U.S. has been estimated to be 29.2% in the last decade (Moreno and Simon, 2017). This condition is characterized by an excessive vaginal discharge, a malodor

due to amines, an elevated vaginal pH (>4.5) and the presence of “clue” cells (squamous epithelial cells covered with adherent bacteria). BV is typically diagnosed using either the Amsel criteria, based on the aforementioned symptoms, or Nugent scoring method, which examines bacterial composition based on the morphotypes and the proportion of Gram-stained bacteria (Smith and Ravel, 2017).

Dysbiosis of vaginal microbiome in reproductive medicine

In contrast to the HMP, which investigated normal healthy volunteers, several studies have looked at the link between vaginal microbiome and infertility. Specifically, BV has been associated with increased risk of acquiring human immunodeficiency virus (HIV) and other sexually transmitted infections. Moreover, obstetric complications such as spontaneous abortion and preterm delivery have been associated to a disbalanced vaginal microbiota with reduced abundance of *Lactobacilli* (Smith and Ravel, 2017).

Using culture-based approaches, a study carried out by Selman and collaborators showed that vaginal-cervical microbial contamination at the time of embryo transfer (ET) is associated with significantly decreased pregnancy rates (Selman et al., 2007). Bacteria such as Enterobacteriaceae and *Staphylococcus*, isolated from the ET catheter, were associated with poor reproductive outcomes. Another study using sequencing-based technology also suggested that the vaginal microbiome on the day of embryo transfer affects pregnancy outcomes. Specifically, they found that low diversity indexes, with *Lactobacillus* dominant microbiota, have better pregnancy outcomes (Hyman et al., 2012). Similarly, a recent meta-analysis showed that BV is associated with a significantly increased risk of preclinical pregnancy loss; while it is not associated with decreased conception rates after IVF treatment (van Oostrum et al., 2013).

Endometrial Microbiome

Historically, the upper genital tract (UGT) had been considered a sterile site. However, endometrial cultures obtained from patients subjected to hysterectomy for benign conditions suggested the presence of microorganisms in the uterus of approximately one-quarter of the women examined (reviewed in Mor et al., 2015). Furthermore, the use of advanced molecular biology techniques has enhanced our understanding of the UGT microbiome.

A recent study by Mitchell et al. (2015) has provided additional evidence that the upper genital tract in asymptomatic women is not a sterile environment. In their study, 95% of endometrial samples analyzed, tested by qPCR for a set of 12 bacterial genes, were positive for at least one species of bacteria. However, the amount of bacterial DNA detected in the upper genital tract was consistently and significantly lower than in their paired vaginal samples, while significant changes were observed in the bacterial species detected in both samples.

Consistent with this work, a recent study performed using sequencing of the 16S rRNA gene has examined the vaginal and endometrial microbiome of asymptomatic and fertile women and has detected bacterial DNA in the endometrial samples of all subjects. Interestingly, about 20% of the women analyzed had different bacterial communities in the uterine cavity and the vagina, showing that the bacteria detected in the endometrium are not a carry-over from the vagina, demonstrating that, although very similar, both microbiomes are not always identical in each woman (Fig. 3). A total of 166 different OTUs were identified in the endometrial fluid samples analyzed from 22 fertile women. The most represented genus was *Lactobacillus* (71.7% of identified bacteria); while *Gardnerella* (12.6%), *Bifidobacterium* (3.7%), *Streptococcus* (3.2%), and *Prevotella* (0.866%) were the other most common genera in endometrial samples (Moreno et al., 2016).

Fig. 3 Number of paired samples with detection of most abundant genera in vaginal aspirate (VA), endometrial fluid (EF) alone, and in both VA and EF. Reprinted from Moreno, I., Codoñer, F.M., Vilella, F. et al., Evidence that the endometrial microbiota has an effect on implantation success or failure. *American Journal of Obstetrics and Gynecology*, **215**(6), 684–703, Copyright 2016, with permission from Elsevier.

The differences observed between the upper and lower genital tract could be explained by the cervix, which serves as a barrier for the ascending bacteria from the vagina to the upper genital tract, and/or by the immune response that is exerted in the cervix to avoid colonization with microbial pathogens. Moreover, these differences could be influenced by the microbial ability to evade the immune response, or even because some microbes may remain in the upper genital tract after disappearing from the vagina and/or have better growth in the upper genital tract (Mitchell et al., 2015).

Uterine microbiome in gynecological diseases and obstetrical complications

Recently the uterine microbiome has also been related to several gynecological conditions. The results from different studies propose bacterial contamination of the endometrium as a potential new factor in the establishment of endometriosis, a disease characterized by the existence of endometrial epithelial and stromal tissue outside the uterine cavity. Lately, there are also studies that show an enrichment of several taxa in the reproductive tract of patients with endometrial hyperplasia and cancer compared to those with benign conditions, pointing to the infectious/inflammatory role of bacteria in the onset of endometrial cancer (reviewed in Moreno and Franasiak, 2017).

On the other hand, the microbiome has also been linked with diseases that affect pregnancy. For example, the chorioamnionitis, an obstetrical complication caused by the inflammation of the fetal membranes, has been linked to polymicrobial infections of microorganisms, which may ascend from the vagina and colonize the intrauterine cavity. In addition, a possible contribution of bacterial infections in the placenta of patients with preeclampsia, an obstetrical condition characterized by high blood pressure, has recently been determined (reviewed in Moreno and Franasiak, 2017).

Endometrial dysbiosis in reproductive medicine

The description of the endometrial microbiota from IVF patients has been attempted using classical microbiological culture. Different studies have linked the isolation of endometrial pathogens such as Enterobacteriaceae, *Streptococcus* spp., *Staphylococcus* spp., *Escherichia coli* and Gram-negative bacteria from the catheter tip at the time of embryo transfer, with significantly reduced implantation and pregnancy rates (reviewed in Moreno and Simon, 2017).

Subsequently, the endometrial microbiome of infertile patients and its functional impact on reproductive outcome have been assessed using 16S rRNA gene sequencing. A recent study has reported the endometrial microbiome at the time of ET in 33 IVF patients. The most represented bacteria found in the overall samples belong to the *Lactobacillus* and *Flavobacterium* genera. However, when the endometrial microbiome of patients with ongoing versus nonongoing pregnancies were compared, none of the OTUs found was able to significantly discriminate between these two groups (Fransiak et al., 2016).

In the most recent study, carried out by Moreno and colleagues (Moreno et al., 2016), the impact of the endometrial microbiome in reproductive function was analyzed. Endometrial fluid (EF) samples were obtained from 35 infertile patients with repeated implantation failure (RIF) presenting receptive endometrium analyzed with the Endometrial Receptivity Analysis (ERA) diagnosis tool ("ERA," www.igenomix.com). The results of this study showed that endometrial microbiota profile can be classified according to the structure and relative abundance of the bacterial OTUs identified in EF samples as *Lactobacillus* dominated microbiome (LD) ($\geq 90\%$) or non-*Lactobacillus* dominated microbiome (NLD) ($< 90\%$), as the percentage of *Lactobacillus*, served as a significant variable to predict the reproductive success (Fig. 4). The presence of a NLD microbiota significantly correlated with decreases in implantation (60.7% vs. 23.1%), pregnancy (70.6% vs. 33.3%), ongoing pregnancy (58.8% vs. 13.3%), and live birth (58.8% vs. 6.7%) rates in comparison to subjects with LD endometrial microbiota.

Chronic endometritis and reproductive function

The best example of pathology caused by an altered endometrial microbiota is chronic endometritis (CE). CE is a persistent inflammation of the endometrial lining caused by the infection of the uterine cavity mainly by bacterial pathogens. The presence of certain microorganisms such as *Streptococcus*, *E. coli*, *Enterococcus faecalis*, *Chlamydia*, and mycoplasma species as *Mycoplasma genitalium* and *Ureaplasma urealyticum* (Kitaya et al., 2016) have been related to the onset of CE in a high percentage of cases.

CE is usually asymptomatic which makes it difficult to estimate their prevalence, calculated for the general population between 0.8% and 19%. In infertile patients the prevalence has been estimated in 0.2%–46%, depending on the population type and the diagnostic criteria used on each study (Peymani and DeCherney, 2016). CE has been diagnosed in 12.9% of patients with miscarriages of unknown etiology and in 30.3% of patients with RIF (Kitaya et al., 2016). There are also studies that determine a higher prevalence of CE, reaching 60% in women with unexplained RM and about 66% of women with RIF (reviewed in Moreno et al., 2016). Matteo and colleagues reported that CE might reduce endometrial receptivity and cause infertility owing to an abnormal pattern of lymphocyte subsets causing an aberrant endometrial microenvironment in CE patients (Matteo et al., 2009).

The standard diagnosis of CE relies on histology, which is based on the identification of plasma cells in the endometrial stroma, sometimes supplemented by immunohistochemical quantification of syndecan-1 (CD138) positive cells. Also, the use of hysteroscopy has been proposed as a diagnostic method for CE by evaluating the presence of micropolyps, stromal edema, or hyperemia. Compared to histological findings, hysteroscopy has a diagnostic accuracy of 93.4% (reviewed in Kitaya et al., 2016), however, none of these methods is able to identify the bacterial pathogen causing such inflammation. The last method of CE diagnosis is the culture of infectious agents from the endometrial cavity, which identifies pathogens associated with the disease, providing information for a targeted therapy. In this case, the infectious agents are isolated upon microbial culture in about 73% of women histologically diagnosed of CE (reviewed in Moreno et al., 2016).

Fig. 4 *Lactobacillus* abundance is a significant variable to predict pregnancy success in IVF patients. Linear discriminant analysis (LDA) showing mean values of the most abundant operational taxonomic units (OTUs) in the receptive subjects grouped by their reproductive success. From data in Moreno, I., Codoñer, F.M., Vilella, F. et al., (2016). Evidence that the endometrial microbiota has an effect on implantation success or failure. *American Journal of Obstetrics and Gynecology*. **215**(6), 684–703.

In case there is no information available on microbiological culture or causative agents, some authors recommend the administration of broad-spectrum antibiotics, such as doxycycline, as the treatment of choice for CE. While treatments based on the antibiogram are critical to select the most effective treatment. This has been seen in recent clinical studies showing an improvement in clinical pregnancy and live birth rates in RIF's patients with CE treated with antibiogram-based antibiotic treatment (reviewed in [Peymani and DeCherney, 2016](#)).

Antimicrobials in Assisted Reproductive Techniques

Although the association between the reproductive tract microbiome and the reproductive outcome remains relatively poorly understood, there is a long history with the use of prophylactic antibiotics during assisted reproductive techniques (ART). Since many years, it has been suggested that microbial contamination during ART could negatively affect the outcomes in this cycle. For this reason, during ART procedures, antibiotics have been proposed as a way to decrease infections of the uterine cavity and thus increase pregnancy rates (reviewed in [Peymani and DeCherney, 2016](#)).

Despite this widespread practice, there are relatively few data supporting or rejecting the usefulness of antibiotics. A recent review analyzing existing data on the effect of antibiotics on reproductive outcomes showed that the administration of antibiotics prior to ET significantly reduced upper genital tract microbial contamination but this was not translated into better pregnancy rates, which were 36% in patients who received antibiotics and 35.5% in those who did not receive them ([Kroon et al., 2012](#)). One possible explanation for the lack of a clear benefit of antimicrobial use prior to ET is that broad-spectrum prophylactic antibiotics may interfere with both dysbiotic bacteria and healthy microbiome, procuring an altered endometrial environment for the ready-to-implant embryo.

For this reason, other ways to restore the physiological reproductive tract microbiome in case of dysbiosis must be explored. In this context, probiotics have been used to increase bacteria with beneficial profiles rather than directly eliminate pathogenic bacteria, since these probiotics present properties antagonistic to pathogens but complementary to host immunity. In fact, these organisms have been associated with conception, reducing the risk of infection, as well as potentially lowering the risk of a number of pregnancy complications ([Reid et al., 2013](#)).

The regeneration of the normal microbiota with the use of probiotics has recently been proposed as a potential therapy for many gynecological and obstetric diseases, either as complementary or as first choice treatment ([Álvarez et al., 2015](#); [Griffin, 2015](#); [Nader-Macías and Juárez Tomás, 2015](#)) (Table 1). In fact, they could be used after antibiotic therapy, with the aim of

Table 1 Possible beneficial effects of the use of probiotics in gynecological and obstetrical conditions

<i>Gynecological and obstetrical conditions</i>	<i>Suggested probiotic</i>	<i>Purpose</i>
Bacterial vaginosis	<i>L. rhamnosus</i> , <i>L. reuteri</i> , <i>L. acidophilus</i> , <i>L. gasseri</i> , <i>L. crispatus</i> , <i>L. fermentum</i> , <i>L. casei</i> , <i>L. bifidus</i> , <i>L. plantarum</i> , etc.	Treatment and prevention
Vulvovaginal candidiasis	<i>L. rhamnosus</i> , <i>L. reuteri</i> , <i>L. fermentum</i> and <i>L. acidophilus</i>	Treatment and prevention

re-colonizing the mucosa before the pathogens can grow again. Specifically, probiotic supplementation with vaginal *Lactobacillus* has been investigated as a way to treat vaginal infections such as BV with efficient results (Recine et al., 2016). Although more functional metagenomic data are needed to characterize the physiological state of the uterine cavity leading to successful pregnancies, this approach could positively affect the outcomes of ART in the future.

Concluding Remarks and Future Perspectives

Knowledge regarding the interactions between the microbiome and the female reproductive tract is rapidly growing thanks to the emerging metagenomic techniques. The progress in the molecular analysis of bacteria has helped to overcome technical obstacles that historically prevented the detection of some bacteria by culture. In addition, these modern technologies allow an analysis that extends beyond phylogenetic descriptions and makes attempts to study the physiology and ecology of the microbiome.

A deeper understanding of normal physiology of the female reproductive tract, the study of biofilms and the identification of different dysbiotic states, could help to characterize the role of the microbiome in reproductive outcomes. All the efforts are now focused on the identification of a microbial signature responsible for reproductive failure or success. The attribution of negative IVF outcome to a specific isolated bacterium is no longer the best option, since to draw conclusions the entire microbial community needs to be addressed. Moreover, rather than trying to eliminate pathogens, nowadays the use of probiotics to restore the beneficial microbiota has been widely suggested. The use of probiotics in the clinical management of infertile patients promises to be a treatment that could improve pregnancy outcomes and prevent obstetrical complications associated with bacterial pathogens, improving thus the clinical care.

Summarizing, the process of implantation is complex and multifactorial, since the reproductive success is not only defined by endometrial histology and gene expression. The ongoing revolution in technology, multiple “-omics”, and multidimensional data analysis has opened the window to a greater level of study. It is time to further investigate the female reproductive tract microbiome and expand research to its virome, fungome, epigenome, and metabolome to increase our 360 degree understanding and to develop targeted therapies. Consequently, the presence of certain microbiome profiles should be considered as an additional risk factor for implantation failure and pregnancy loss, which highlights the importance of using microbiological assessment and probiotic treatments to improve and personalize IVF procedures.

Glossary

Chronic myeloproliferative syndromes Are characterized by a clonal evolution associated with a significantly variable course, which may be complicated by thrombocythemia, (secondary) myelofibrosis, and finally acceleration (unstable phase) that merges into blastic crisis. Include as main subtypes polycythemia vera (PV), chronic idiopathic myelofibrosis (IMF), and essential thrombocythaemia (ET).

Factor inhibitor Inhibitors are a serious medical problem that can occur when a person with hemophilia has an immune response to treatment with clotting factor concentrates.

Hemophilia A Also called factor VIII (FVIII) deficiency or classic hemophilia, is a genetic disorder caused by missing or defective factor VIII, a clotting protein. Although it is passed down from parents to children, about 1/3 of cases are caused by a spontaneous mutation, a change in a gene.

Infertility Is defined as difficulty getting pregnant.

Miscarriage Is defined as a spontaneous abortion.

Primary immune thrombocytopenia (ITP) Is an acquired immune-mediated disorder characterized by isolated thrombocytopenia, defined as a peripheral blood platelet count less than 100,000 in the absence of any obvious initiating or underlying cause.

Thrombocytosis Is a disorder characterized by abnormally high levels of platelets in the blood, more than 450,000.

Von Willebrand disease Is a genetic disorder caused by missing or defective von Willebrand factor (VWF), a clotting protein. VWF binds factor VIII, a key clotting protein, and platelets in blood vessel walls, which help form a platelet plug during the clotting process.

Basis of Coagulation

The haemostatic system consists of blood vessels, platelets, and the plasma coagulation system including the fibrinolytic factors and their inhibitors. When a blood vessel is injured, three mechanisms operate locally at the site of injury to control bleeding: vessel wall contraction, platelet adhesion and aggregation (platelet plug formation), and plasmatic coagulation to form a fibrin clot. All three mechanisms are essential for normal hemostasis. Abnormal bleeding usually results from defects in one or more of these three mechanisms. For a better understanding of the pathogenesis of pathological bleeding, it is customary to divide hemostasis into two stages (i.e., primary and secondary hemostasis). Primary hemostasis is the term used for the instantaneous plug formation

upon injury of the vessel wall, which is achieved by vasoconstriction, platelet adhesion, and aggregation. The fibrin formation is not required for hemostasis at this stage.

Screening and Diagnosis of Coagulation Disorders in Women

After clinical assessment and family history, the clinician often has a general overview concerning the cause of a patient's bleeding or thrombosis. Routine screening tests include a complete blood cell count, platelet count, and evaluation of a peripheral blood sample, a prothrombin time, and an activated partial thromboplastin time. Thrombocytopenia may be due to an Immune Thrombocytopenic Purpura (ITP), and thrombocytosis to a chronic myeloproliferative syndrome. Again, the patient's history, physical findings, and evaluation of a well-prepared peripheral blood smear will be helpful in determining the cause of the patient's thrombocytopenia or essential thrombocythaemia (Lusher, 1996). (See Table 1)

An isolated prolongation of the activated partial thromboplastin time may result from low levels of factors VIII, IX, or XI. A slightly prolonged activated partial thromboplastin time (aPTT) and a moderate decrease in factor VIII may reflect von Willebrand disease (VWD) or the "carrier" state for hemophilia A. In women a greatly prolonged aPTT and very low levels of factor VIII (<3%) most often result from an acquired factor VIII inhibitor (autoantibody against factor VIII) or from severe (type III) of VWD. Also, a prolonged Prothrombin Time (TP) might be observed in other rare bleeding disorders, such as Factor VIIc or Factor X deficiency.

The thrombophilia study includes the following determinations: antithrombin (AT), plasma protein C (PC), antigenic and free protein S (PS), due to functional PS is no longer required as it leads to false diagnoses, functional fibrinogen, antiphospholipid antibodies (APL): lupus anticoagulant (LA), anticardiolipin antibodies (ACL), anti-β2-glycoprotein 1 antibodies (β2GP1), homocysteine, activated protein C resistance (APCR) and Factor VIII. The genetic study includes: Leiden V factor (LVF), prothrombin G20210A mutation (PTM) and ABO Genetic Group.

In the high-risk genetic study to increase the chances of diagnosing patients with hereditary thrombophilia, could be included: F12 Mutation, AT Cambridge Mutation (A384S mutation in the SERPINC1 gene), R67X mutation in the SERPINA10 gene, fibrinogen mutation. If the RPCA is normal, is recommended to perform LVF, if the RPCA is positive but FVL negative, perform factor V Cambridge and Hon Kong mutations (see Table 1).

Bleeding Disorders: Impact on Fertility

Prevalence and Consequences

Women suspected of having a bleeding disorder (or who are hemophilia carriers) should undergo diagnostic testing before becoming pregnant to ensure appropriate preconception counseling and pregnancy management. Bleeding disorders also are more prevalent in women with menorrhagia, and prevalence ranges from 10% to 100%, depending on the specific bleeding disorder. During pregnancy, women with bleeding disorders may have an increased risk of bleeding complications. At delivery, affected women are more likely to experience postpartum hemorrhage, particularly delayed or secondary postpartum hemorrhage.

Women can be affected by several different bleeding disorders such as VWD; platelet defects; Hemophilia A, B or C; and other more rare clotting deficiencies, as well as disorders involving the fibrinolytic system (Kadir and James, 2009).

The prevalence of bleeding disorders in females is unknown. However, VWD, the most common bleeding disorder in humans, may affect between 1% and 2% of the general population. Among those women seeking medical care for menorrhagia, the incidence of VWD or another bleeding disorder may be as high as 20%.

Von Willebrand Disease

VWD is the most common inherited bleeding disorder, and it affects men and women equally. VWD follows an autosomal dominant inheritance pattern. In VWD the defect is in vWF. The affected individual may have abnormal levels of structurally and functionally normal vWF (this is called "classic" or type I VWD) or may produce vWF that is structurally and functionally abnormal (VWD type II). Individuals who inherit a gene for VWD from both parents have severe (type III) VWD, will have extremely low levels (<3%) of vWF and factor VIII and will have a very prolonged bleeding time. In most populations type I disease is the most common form, whereas type III is the least commonly encountered form. It should be noted that levels of vWF can be

Table 1 Screening and diagnosis of coagulation disorders in women

Coagulation study	Result	Possible hemostatic disorders
Platelets count	Thrombocytopenia Thrombocytosis	ITP, vWD cMPS
Prolonged aPTT	LA FVIIIc, FXIc; FIXc, FIIc, FXc, vWF	Autoimmune disease Rare bleeding disorders such as Haemophilia, or vWD
Prolonged TP	FIIc, FVc, FVIIc, FXC	Rare bleeding disorders

influenced by the patient's blood type (persons who have blood type AB have 60%–70% higher levels than persons who have blood type O) and can be elevated during pregnancy, stress, and hyperthyroidism. The two major functions of vWF are to serve as a “bridge” between platelets and injury sites in blood vessel walls and to protect circulating factor VIII from rapid proteolytic degradation. Thus, if a patient has either too little or functionally abnormal vWF, the bleeding time will be prolonged and factor VIII will be decreased (because it is not being protected by vWF). It should be determined which type of von VWD a particular patient has because treatment depends on the type. Multimeric analysis of vWF can be done, and this will allow visualization of the multimeric structure of vWF. In type I disease all bands are present, whereas in the type II variants: 2A and 2B no high-molecular-weight multimers are seen.

Symptomatic Carriers of Hemophilia

Women who are genetic carriers of hemophilia A or B have one gene affected by hemophilia and one that is unaffected. Factor VIII or IX levels that are approximately half of normal are not unusual among hemophilia carriers. Women are found to be hemophilia carriers after giving birth to a son with hemophilia and having genetic testing. A woman whose father has hemophilia is considered an “obligate carrier”, since the only X chromosome that can be given by the father is affected with the disease.

Factor VIII or IX levels in female carriers have been reported to range from 4% to 80%, with levels of 40%–60% being common. Female carriers who have lower than normal factor levels may be considered to be persons with mild hemophilia ([Kupferminc et al., 1999](#)).

Women With Hemophilia

Although rare, cases of severe Hemophilia A and B are found in women. These cases usually fall into one of two categories. Either the woman inherited a hemophilia gene from both her father with hemophilia and her mother who is a carrier, or she is a genotypic carrier who has experienced extreme lyonization of the hemophilia gene, causing the woman's normal gene for the production of Factor VIII or Factor IX to be “turned off.” Women who have moderate to severe hemophilia will have bleeding similar to that of males with the same degree of severity of hemophilia, with the added feature of gynecologic and obstetric problems that make clinical management much more challenging.

Rare Bleeding Disorders in Women

Factor XI deficiency is a very rare bleeding disorder, also called Hemophilia C, it affects approximately 1 in 100,000 people in the United States. Factor XI deficiency follows an autosomal dominant inheritance pattern, meaning that males and females are equally affected. Very little is known about Factor XI deficiency. Prolonged bleeding may occur with surgeries, dental extractions and injury, similar to the bleeding that occurs with VWD. Other rare factor deficiencies may be found in women, like factor V, factor VII, factor X and factor XIII deficiencies, all may produce excessive bleeding. Afibrinogenemia, also called factor I deficiency, may produce severe bleeding symptoms. Dysfibrinogenemia is a disorder in which fibrinogen is found in lower quantity as well as an abnormal quality, leading to prolonged bleeding. The factor XIII deficit causes recurrent abortions and should be discarded.

Obstetric Complications in Women With Bleeding Disorders

Women with bleeding disorders should be able to conceive and carry a pregnancy to term and experience a safe delivery. Managing the pregnancy of a woman with a bleeding disorder requires a multidisciplinary team that will consider the risk of bleeding for the mother and baby. Multiple methods exist for the definitive prenatal diagnosis of hemophilia. Unfortunately these methods are all invasive and may place the woman at risk for excessive bleeding. Amniocentesis, chorionic villus sampling, and cordocentesis must all be undertaken with awareness of the risk of bleeding and/or miscarriage. Conditions such as VWD and platelet dysfunctions are not easily diagnosed before the birth of the infant. Fetal sex determination can be useful in the management of pregnancies at risk for hemophilia, for example, the discovery that a fetus is female may be reassuring to the parents who will know that invasive prenatal testing is not required. When a male child is expected, the delivery can be planned to avoid instrumental deliveries and trauma to the infant during the birth process. Preimplantation genetic diagnosis is a high-tech technique that allows embryos created using in vitro fertilization (IVF) to be tested to determine which are affected by hemophilia. The unaffected embryos are then implanted, avoiding the difficult decision of whether to interrupt a pregnancy because of hemophilia. There have been reports that some women who are carriers of hemophilia have used this method of reproduction to be sure that they will have a child who is not affected with the condition. IVF is an expensive therapy, so the costs of the procedures need to be considered when planning its application. Since normal pregnancy is accompanied by increased levels of several clotting factors and a decrease in fibrinolytic activity, pregnancy is considered a hypercoagulable state.

These women will require treatment to prevent bleeding and to maintain the pregnancy. Infertility is defined as difficulty getting pregnant. Many women with bleeding disorders report having trouble getting pregnant. There is little research to report the incidence or the cause of infertility in women with bleeding disorders. In addition, many women with bleeding disorders report that they have experienced miscarriage. It is unknown whether this can be attributed to their bleeding disorder. It is known that

women with bleeding disorders who have miscarriages are at risk for serious bleeding due to the precipitous drop in factor VIII and vWF levels that occur soon after the loss of a pregnancy. Good hematologic care is advised during and after miscarriage

Primary Immune Thrombocytopenia and Pregnancy

The prevalence of ITP during pregnancy has been reported to be 1 in 1000 to 10,000. In affected patients, despite the potential haemostatic challenges of pregnancy—a time when clotting factors are elevated—platelet counts drop by approximately 10%. During pregnancy, therefore, women with ITP are vulnerable to exacerbation or relapse.

Although the concept is counterintuitive, ITP is a hypercoagulable state. Patients with ITP have approximately a 1.6-fold increased risk of venous thromboembolism (VTE) and a 1.4-fold increased risk of arterial thrombosis. Especially if other risk factors are present, women with ITP may benefit from some form of thromboprophylaxis at delivery, such as use of pneumatic compression devices.

Thrombophilia and Reproduction

What Is Thrombophilia?

Thrombophilia is the tendency to thrombosis. Thrombosis is a complex multifactorial disease, in which multiple interactions between genetic and environmental factors contribute to the development of the disease. Therefore, thrombophilia may be hereditary or acquired, for example, there are thrombophilic genetic mutations (LVF) and other thrombophilic factors or phenotypes (gene-environment interaction) that may be hereditary (like factor VIII) or acquired (APL). There are different phenotypes that have been related to thrombosis, such as APCR, homocysteine, etc. We currently know more than 15 genetic factors and phenotypes associated with venous thrombosis. The association of haemostatic phenotypes (such as RPCA) and risk of thrombosis has been studied, and later search for genetic polymorphisms associated with these risk phenotypes (Factor V Cambridge or factor V Hong Kong, etc.). But nowadays, only 40%–50% of the causes of venous thrombosis are known ([Robertson et al., 2006](#); [Souto et al., 2000](#)).

Thrombophilia and Venous Thromboembolism

Pregnancy is a prothrombotic state per se, it is estimated that the risk of VTE in a pregnant woman during gestation and the puerperium is five times higher than that of a woman who is not pregnant. In addition, presenting thrombophilia, as we will see below, is an added risk factor for thrombosis or repeated miscarriages (RM). Thrombophilia has been linked to infertility, and placental thrombosis with RM.

In the case of fertility treatments, the risk of thrombosis is multiplied. The risk is 10 times higher in women who undergo IVF than women who have a natural pregnancy, and if there is ovarian hyperstimulation syndrome, the risk increases up to 100 times ([Robertson et al., 2006](#); [Bovill et al., 1999](#); [Rosendaal, 1999](#)).

Thrombophilia and Placenta Mediated Complications

Thrombophilia has been proposed as a factor related to gestational complications or placenta mediated complications (PMC). The TREATS study showed that women with thrombophilia were more at risk of developing PMC ([Robertson et al., 2006](#)). The hypothesis is that thrombophilia is a situation that predisposes to a state of hypercoagulability and a tendency to thrombosis, and this could be implicated in gestational complications related to vascular dysfunction, as these complications are due in part to the presence of placental thrombosis. In addition, many factors of coagulation are involved in the correct formation of the placenta such as AT or ANXA.

What prothrombotic factors have been described at present and what evidence is there currently of the association with infertility?

We summarize below the main markers of thrombophilia and the current evidence on their implication in PMC (see [Table 1](#)).

Activated protein C resistance and Leiden V factor

Activated protein C is the most potent endogenous anticoagulant. In 1993, APCR was described as a mechanism responsible for familial thrombophilia. The APCR is an intermediate phenotype associated with the risk of presenting venous thrombosis characterized by a low anticoagulant activity of the protein C system. One year later, at the University of Leiden (The Netherlands), the cause of most cases of hereditary APCR was identified. Although the LVF mutation has been identified as the main cause of this plasma alteration, still 10%–20% of cases of APCR are not carriers of the LVF mutation, indicating the presence of other mutations that cause the same phenotype. Among them, FV Cambridge and FV Hong Kong are genetic variants affecting the amino acid Arg306, which also alter the activation of the PC system. A normal APCR does not exclude the presence of LVF, and if there is an elevated APCR with a normal LVF, it is important to perform a Hong Kong VF, or Cambridge VF. However, there are no studies showing association between these mutations and PMC ([Rai et al., 2002](#)) ([Table 2](#)).

• R67X mutation in <i>SERPINA10</i> gen
• Fibrinogen mutation
• Haplotype ANXA M2

Prothrombin mutation 20210A

Prothrombin is a coagulation factor, precursor of thrombin that activates the coagulation factors V and VIII and converts fibrinogen to fibrin. A mutation in the prothrombin gene, located on chromosome 11, was identified in 1996 in patients with familial thrombophilia, and is associated with a 3 to 5-fold increased risk of thrombosis. The presence of this mutation is associated with a 2 to 3-fold risk of presenting PMC although some studies have not described this association.

Moderate hyperhomocysteinemia

Moderate hyperhomocysteinemia is a risk factor for VTE. The results on whether the thermolabile mutant form of MTHFR is associated with an increased risk of VTE have shown that it is not a cause of thrombosis and therefore should no longer be performed (Robertson et al.). There are studies that demonstrate the association of moderate hyperhomocysteinemia and PMC, in these cases, it is very important to rule out the presence of vitamin B12 or folic acid deficiency, since the treatment of these can resolve the problem. Studies seem to correlate hyperhomocysteinemia with PMC.

Antithrombin deficiency

Antithrombin is an endogenous anticoagulant that blocks the biological activity of thrombin and activated factors IX, X, XI, and XII. Hereditary deficit is not very prevalent, but up to 50% may develop thrombosis. Women with AT deficiency have an increased risk of PMC in addition to having a high risk of thrombosis during pregnancy.

Protein C and Protein S deficiencies

Protein C and protein S deficiencies are inherited in an autosomal dominant manner. Hereditary deficiencies were associated with a VTE risk of 2.5% and 1.3%, respectively. The TREATS study demonstrated association with the presence of PMC.

C46T mutation in the F12 gene and factor XII levels

The C46T mutation of F12 is a risk factor for venous or arterial thrombosis. Factor XII is essential at the onset of the blood coagulation cascade. The concentration of this protein in plasma, or what is the same, this intermediate phenotype, has a significant positive genetic correlation with thromboembolic disease. And it is known that the C46T mutation in the F12 gene is a risk factor and correlates with factor XII levels. In addition, carriers in homozygous T allele have a 5-fold increased risk of thromboembolic events than noncarriers. However, association studies between mutation and factor XIIc levels are inconclusive today.

ABO blood group and factor VIII increase

It has been known since the XX century that carriers of the blood group other than O (No-O) have a 2- to 4-fold higher risk of thrombotic events.

This relationship has been established through the association between the ABO group and factor VIIIc levels, on the one hand, and vWF levels, on the other hand. The non-O blood group presents a 2- to 4-fold higher risk of thrombosis. In addition, the blood group is associated with factor VIIIc levels. And within the genetic blood group, it is known that being a carrier of the allele A1

implies more risk of thrombosis. Finally, in the non-O group, the levels of factor VIIIc has been associated with the onset of thrombosis and could also be associated with RM, although as with previous factors further studies are needed to corroborate these findings.

Haplotype ANXA M2

Annexin-A5 (ANXA5) is an anticoagulant protein that has been postulated as a cause of thrombosis, and is also expressed in the placenta. Its action on the placenta may be affected by APL against it, and the presence of anti-ANXA5 antibodies has been associated with the development of abortions. In addition, a haplotype has been described by the ANXA5 M2 that is associated with a reduction in expression in this protein, and may increase the risk of thrombosis, and it has also been studied that its decrease in the placenta causes inadequate placentation, and therefore is associated with abortions. Genetic transmission may be paternal or maternal. Currently, it is being studied whether it could be a biomarker for the use of personalized antithrombotic therapy.

Other thrombotic risk factors

Other factors of coagulation or fibrinolytic system may be involved in the predisposition to thrombosis. Dysfibrinogenemia, dysplasminogenemia, hypoplasminogenemia, are exceptional causes of familial VTE. And these in turn are associated with PMC problems. From the genetic point of view, there are many polymorphisms in different candidate genes (most of which encode the aforementioned proteins) that are being subjected to multiple association studies to determine their involvement in VTE. Regarding the association with PMC, in the majority of studies the association between FVL, PT20210A and gestational losses has been studied, but in the rest of hereditary thrombophilias there are studies that have shown association and others that have not. In addition, studies are currently under way with the ANXA M2 haplotype to determine if this would be the biomarker that would establish, in the presence or not of thrombophilia, or other factors involved in miscarriage, the need for antithrombotic treatment (Fishe et al., 2016).

Acquired Thrombophilia and Placenta Mediated Complications

Interest in the association between thrombophilia and recurrent abortions arose once antiphospholipid syndrome (APLS), considered being an acquired thrombophilia, was found to be a significant and treatable cause of recurrent miscarriage. Therefore, obstetric antiphospholipid syndrome (OAPLS) is the most well-known and studied acquired cause of thrombophilia. APLS is one of the known causes of gestational loss. The most common obstetric manifestation of APLS is recurrent gestational loss, 10%–15% of women with this manifestation are diagnosed with APLS. Patients with APLS have an 80% risk of having an abortion. Fetal death is associated more powerfully than the earliest losses. All women with recurrent first-trimester abortions should be asked for APL.

The APLS is a systemic autoimmune disease mediated by antiphospholipid antibodies (APL)—lupus anticoagulant (LA), anticardiolipin antibodies (ACL) and anti- β 2-glycoprotein 1 (β 2GP1) antibodies—with clinical, diagnostic criteria—analytical, well defined. APL can be detected in 1%–5% of healthy women. The prevalence of these antibodies increases to 15% in women with recurrent miscarriages in the first trimester. A, APLS should be suspected in all women with systemic lupus or other connective diseases who wish to become pregnant and women with a personal history of: recurrent miscarriages; retarded intrauterine growth; fetal death; hypertension, severe preeclampsia or eclampsia, before 34 weeks in particular; *abruptio placentae*; preterm delivery before the 34th week of gestation; analytical alterations such as hemolysis, elevation of liver enzymes or thrombopenia, is suggestive of HELLP syndrome (Danza et al., 2012; Miyakis et al., 2006).

Malignant Hematological and Fertility

Among the causes to be ruled out, it is important to know myeloproliferative syndromes such as essential thrombocythaemia associated with the presence of the JAK-2 mutation or Polycythemia Vera that can be treated with thrombocytosis and JAK-2 positive.

Myeloproliferative Diseases

Myeloproliferative syndromes (cMPS) are associated with an increased incidence of haemorrhagic and thromboembolic complications as well as progression to myelofibrosis and acute myeloid leukemia. Although cMPS have a peak incidence in the sixth and seventh decade of life, they can occur in women of childbearing age (traditionally 15–45 years). Essential thrombocythaemia (ET) is the most commonly reported cMPS in younger women with an increased prevalence in the third decade. Thrombosis is the main cause of morbidity and mortality: blood rheology, possibly relating to leukocyte adhesion, platelet activation and platelet-leukocyte aggregates, is believed to have a leading role in the development of these complications.

The management of cMPS in pregnancy is complicated. A number of studies have shown that women with ET are at higher risk of developing pregnancy complications. Key challenges include the increased risk of maternal hemorrhage, thrombosis and pregnancy loss (Randi et al., 2014). The principal factors influencing pregnancy outcome include an adequate placental development and the maintenance of a normal uterine blood flow.

Thrombosis Risk Factors in Essential Thrombocythaemia

ET during pregnancy is associated with thrombosis of the placental vessels and can lead to multiple infarcts and secondary placental insufficiency. All this causes a risk of miscarriages in the first trimester of pregnancy of between 25% and 40% (it varies depending on the type of study), an increase compared to the general population, which is around 15%. Other complications during pregnancy are placental abruption, preeclampsia, stillbirth or intrauterine fetal death (Alimam et al., 2016).

The relevance of JAK2V617F mutation as a thrombotic risk factor is still debated, as well as the role of platelet and white blood cell counts. There is controversy as to whether the presence of the JAK2V617F mutation favors thrombotic events. Some studies reported a higher incidence of miscarriages in JAK2V617F positive patients with ET than in JAK2-negative cases (Passamonti et al., 2007), while the Mayo Clinical study demonstrate similar rate of pregnancy loss between JAK2 mutated and nonmutated patients. There is no direct correlation between platelet count and the presence of complications during pregnancy.

History of Surgical Evaluation of Infertility

Up until the 1970s, most operations required large incisions for the surgeons to be able to view the pelvis and have room to operate. These large incisions were often painful to recover from, took weeks to heal, and put the patient at more risk of complications. Subjecting infertile but otherwise healthy women to the risks of “open” surgery and the large incisions it requires would have exposed them to greater risk than potential benefit and would violate the principle of “First, do no harm.” Today, gynecologic surgeons can choose from a variety of endoscopic instruments to safely visualize and operate within the abdomen, pelvis, uterus, bladder, and rectum with relatively little downtime for the patient. Surgery can now be performed through small surgical incisions and using a variety of telescopic cameras (videolaparoscopy), and videolaparoscopic instruments. Early instruments were simple tubes through which a surgeon could peer into the abdomen or vagina and were known as endoscopes. They allowed for some diagnostic procedures but were unsuitable for anything but the most rudimentary operative procedures (Nezhat et al., 2013).

Dr. Camran Nezhat’s invention and development of video-assisted endoscopy in the 1970s and early 1980s that transformed the landscape of surgery as we know it today. These instruments use high-resolution video cameras to record, magnify, and display the operative view on monitors to the entire surgical team. Having once been relegated to uncomfortable positions in order to peer through the endoscope, surgeons could now operate in relative comfort and ease and begin performing advanced procedures. In the United States, the vast majority of pelvic surgery is performed videolaparoscopically due to its superior visualization, low morbidity, and increasing surgeon competency (Stovall et al., 2006). Videolaparoscopy is the standard of care for minor gynecologic procedures and is the preferred approach for a sizable number of more complex procedures.

In the course of an infertility workup, imaging studies such as ultrasound and hysterosalpingogram are performed in favor of an exploratory surgery known as diagnostic videolaparoscopy and never be surgically evaluated for endometriosis. Recent data suggests that videolaparoscopic resection of endometriosis can drastically improve pregnancy rates in women with infertility refractory to IVF (Littman et al., 2005; Burney and Nezhat, 2008).

Standard and Specific Pre-Operative Workup

Infertile couples are asked to provide thorough medical, reproductive, and menstrual histories and undergo physical exams. Samples of blood, urine, and semen are analyzed to screen for medical and genetic conditions that could impact a couple’s fertility. Laboratory and imaging studies are further detailed in the medical and radiologic work up chapters. When these studies are unable to establish the cause for infertility, or in cases where the physical exam or imaging studies indicate surgically treatable conditions, surgical evaluation and treatment is offered. In order to reduce the risk of multiple surgeries and optimize a patient’s chances at conception, patients are often consented for simultaneous diagnostic and operative procedures (Nezhat et al., 2013).

Intraoperative Layout

Once the patient has undergone a pre-operative assessment, is medically cleared, and informed consent has been obtained, preparations for surgery begin. Careful consideration must be given to patient positioning during surgery to avoid falls, nerve injuries sustained from being kept in the same position for long periods of time, and inadvertent injury while the patient is asleep.

In gynecology, the patient is typically positioned in dorsal lithotomy (lying on their back with legs separated and positioned in stirrups). In videolaparoscopy, a right-handed surgeon stands to the left of the patient, with their assistant directly across, and sometimes an additional assistant for uterine manipulation. A monitor may be placed by the patient’s legs or by the assistant.

In hysteroscopy, the patient is placed in lithotomy position and the surgeon is between the patient's legs with a screen within easy view (Nezhat et al., 2013). Ultimately, patient safety is tantamount to operating room procedures and variations from these conventions occur to make appropriate accommodations to care.

Hysteroscopic Evaluation

Hysteroscope

Hysteroscopy allows a gynecologic surgeon to visualize and operate upon the inside of the uterus. It is regarded as the gold standard against which other uterine imaging modalities are compared. It requires a hysteroscope, which can pass through the cervix and into the endometrial cavity. The hysteroscope has a channel which allows for fluid under pressure to be instilled into and drained from the endometrial cavity, which allows the uterus to distend. Light shines into the cavity of the uterus through fiberoptic cables and a video camera is connected to back of the hysteroscope and relays high-definition video to a nearby monitor. Thin and flexible hysteroscopes are < 4 mm in diameter and are used primarily for simple outpatient office diagnostic procedures. Thicker, rigid hysteroscopes are often 5 mm in diameter and have an extra channel for the introduction of thin surgical instruments including scissors and graspers. When connected to an energy source, these instruments allow for a gynecologic surgeon to cut, cauterize, and resect or remove tissue from the inside of the uterus and therefore hysteroscopes with this function are termed resectoscopes (Nezhat et al., 2013).

Office Versus Operating Room

Many diagnostic hysteroscopic procedures and operative procedures can now be performed in the outpatient clinical setting. These in-office hysteroscopy procedures may be performed with mild to moderate sedation, with administration of a non-steroidal anti-inflammatory with or without an oral benzodiazepine, or with a simple paracervical block (injection of numbing medication near the cervix). Many patients and providers prefer the office hysteroscopies as they are lower cost, do not require general anesthetic, and do not require use of an operating room in a surgery center or hospital. The vast majority of hysteroscopies, however, still take place in operating rooms and may be incorporated into other planned gynecologic surgeries. Pre-operative ultrasound is often used to guide the surgeon towards anticipating what pathology they may encounter, and preoperative MRI is an option to help define any anomalies of the uterus and specify fibroid characteristics and location. Saline infusion sonogram and hysterosalpingogram are also useful aides to determine whether simple polyps or more complex endometrial pathology is suspected. Such imaging can help a physician predict whether the hysteroscopy will need to take place in the operating room or whether an office procedure would be sufficient (Nezhat et al., 2013).

Timing

Hysteroscopy requires good visualization of the inside of the uterus. Menstrual blood and prolific endometrial tissue can obscure this view, so the gynecologist will time the procedure during the early to mid-follicular phase of the patient's menstrual cycle; just after menses is completed. This also serves to reduce the possibility of disturbing a very early pregnancy. Alternatively, the gynecologist may start the patient on oral contraceptives to thin the endometrial lining (Nezhat et al., 2013).

Cervical Dilation

In order to safely pass the hysteroscope through the cervix and into uterus, surgeons first dilate the muscular cervix. This process can start the night before with the placement of misoprostol tablets into the vagina. Misoprostol is a synthetic prostaglandin medication that softens or "ripens" the cervix in preparation for the procedure. Then the surgeon passes a series of lubricated mechanical dilators through the cervix, gradually increasing in size until the hysteroscope can be introduced.

Procedure With Diagnostics

Once the surgeon has introduced the hysteroscope, and distended the uterus with sterile fluid, they survey the endometrium. By using a rotatable 30 degree angled scope, the surgeon can focus upon any surface within the uterus, as well as the tubal ostia.

When performing hysteroscopy for evaluation of infertility, the anatomic structures within the uterus must be carefully assessed. As many as 25%–35% of patients presenting with infertility are found to have abnormalities in the uterus or fallopian tubes (Abrao et al., 2013). A variety of endometrial pathologies may negatively impact fertility, including endometrial polyps, fibroids, intrauterine cavity adhesions, and Müllerian abnormalities such as a uterine septum. The surgical correction of intrauterine abnormalities, including polypectomy, septoplasty, and submucosal fibroid resection, are associated with improved pregnancy rates.

A tremendous benefit of hysteroscopy is the ability to diagnose and treat many forms of uterine pathology simultaneously. Grasping forceps can facilitate targeted removal of endometrial polyps and scissors can be used to resect intrauterine adhesions and septi. Submucosal fibroids can be shaved down with unipolar loop electrode or technologies such as the Myosure®. Biopsies can be obtained for any suspicious lesions or growths and subsequently sent to pathology for analysis (Nezhat et al., 2013; Perez-Medina et al., 2005).

Endometrial polyps represent the most common intracavitary finding in infertile patients, with the reported incidence of polyps ranging from 10% to 32% (Shalev et al., 2000; Hinckley and Milki, 2004). Most commonly found near the uterine fundus and cornua, polyps are benign irregularly shaped outgrowths that can range in size from millimeters to lesions that completely fill the entire uterine cavity. As some other gynecologic pathologies can have a polyp-like appearance, such as endometrial overgrowth (termed hyperplasia) or malignancies, it is imperative to send removed polyps for pathological analysis. Resection of endometrial polyps can improve fertility outcomes, with infertile women having nearly twice the likelihood of achieving pregnancy following a polypectomy (Perez-Medina et al., 2005).

Leiomyomata, or uterine fibroids, are the most common benign smooth muscle tumors of the uterus with a prevalence of 30%–50% in the population, with some women genetically predisposed to developing fibroids (Stein and Ascher-Walsh, 2009). Their impact upon fertility is dependent on their size, location and number. Their size can range from sub-centimeter to massive growths large enough to fill a woman's entire abdomen. Fibroids are categorized based on their location within the uterus. Pedunculated fibroids are attached only by a narrow stalk to the surface of the uterus. The subserosal variety typically bulge out on the outer surface of the uterus. Neither subserosal nor pedunculated fibroids are meaningfully associated with infertility or heavy menstrual bleeding as they do not impact the endometrial cavity. Intramural fibroids masses within the muscular wall of the uterus. Submucosal fibroids are located just under the surface of the endometrium and are thought to decrease fertility by occupying space within the uterine cavity, leaving fewer areas for implantation of an embryo. In addition, implantation at the site of a fibroid may lead to miscarriage due to decreased vascular flow or abnormal placentation affecting the future pregnancy. They can cause heavy bleeding during menses, and women can become severely anemic. During hysteroscopy, submucosal fibroids appear as rounded masses that bulge into the endometrial cavity. Using a variety of cutting, cauterizing, and suction instruments, submucosal fibroids can be removed at time of hysteroscopy (Nezhat et al., 2013). For subserosal and pedunculated fibroids, see the "Videolaparoscopy" section.

With a prevalence of 2%–3%, *uterine septi* represent the most common congenital anomaly of the uterus. They can range from a thin strip of pale fibrous tissue at the fundus of the uterus to a full-length wall of tissue separating left and right side of the uterus into two entirely separate compartments. Uterine septation is associated with miscarriage in up to 79% of pregnancies, but when detected and resected by hysteroscope, this miscarriage rate decreases to 14% (Hinckley and Milki, 2004). Depending upon its size and thickness, a uterine septation can typically be removed with hysteroscopic scissors, laser, or a unipolar loop electrode.

Hysteroscopically, intrauterine adhesions or *synechiae* are found in up to 21% of women with recurrent pregnancy loss, and in 16% of infertile women prior to starting IVF (Homer et al., 2000). They appear as filmy, white, or devascularized tissue stretching between the endometrium across the uterine cavity. Their presence can prevent the normal fluid distention of the uterus during hysteroscopy, so the uterine cavity can appear collapsed or distorted. Also known as Asherman's syndrome, intrauterine adhesions typically form as a result of mechanical or infectious damage to the endometrium. Most commonly, adhesions form secondary to dilation and curettage (D&C) performed after complications arising from missed or incomplete miscarriage, therapeutic abortion, or retained placenta in the postpartum period. Women with multiple D&Cs or a history of other uterine surgeries such as cesarean section and myomectomy are also at risk of Asherman's syndrome. The incidence of intrauterine adhesions can be as high as 40% following the curettage of retained products of conception; whereas hysteroscopic resection of multiple submucosal uterine fibroids has been associated with a 45.5% incidence of intrauterine adhesions. Following surgical resection of intrauterine adhesions, pregnancy and live birth rates vary between 32% and 76% (Nezhat et al., 2013; March, 2011).

Videolaparoscopic Evaluation

Videolaparoscopy

Videolaparoscopy is a minimally invasive surgical procedure whereby a surgeon can visualize and operate upon abdominal and pelvic organs through several 3–10 mm incisions. Small plastic or metal ports are introduced through the incisions, into the abdomen, and the abdomen is filled with carbon dioxide gas to permit room for the laparoscope and instruments. The laparoscope makes use of fiber optic lighting, a zero degree or angled lens, and a video camera to relay high-definition video from inside the abdomen to a monitor outside of the body. Most surgeries that used to require laparotomies can now be performed videolaparoscopically by expert gynecologists and minimally invasive surgeons. Videolaparoscopic techniques have become the gold-standard for many abdominal and pelvic surgeries (Nezhat et al., 2013).

In contrast to hysteroscopy which can be performed within an office setting, videolaparoscopic procedures almost exclusively require a patient to be under general anesthesia and take place in an operating room. Diagnostic videolaparoscopic procedures make use of at least a single abdominal incision and port, typically through the umbilicus, to thoroughly evaluate the abdominal and pelvic organs. Diagnostic videolaparoscopic procedures can be easily converted to operative videolaparoscopic procedures by the addition of extra-abdominal ports for the passage of videolaparoscopic instruments. These long and thin instruments allow for a surgeon to operate within the abdomen and pelvis.

When performing a diagnostic videolaparoscopic evaluation for infertility, it is customary to attach a uterine manipulator inside the uterus which enables a surgical assistant to move the uterus and helps the surgeon visualize and operate on the entire pelvis and all sides of the uterus. If a manipulator is used that has a channel for instilling fluid, chromoperturbation with dilute methylene blue dye can also be performed during the videolaparoscopic evaluation (Nezhat et al., 2013).

Once abdominal access has been obtained, diagnostic videolaparoscopy begins with careful examination of the bowel, small intestine, and adjacent structures to ensure no damage occurred as a result of the initial port placement, given over 50% of all videolaparoscopic injuries occur at the time of abdominal entry (Vilos et al., 2009). Prior to focusing attention on the pelvis, it is important to perform a thorough evaluation of the abdomen for any pathologic adhesions or disease, which may suggest a history of pelvic inflammatory disease (PID) or the presence of endometriosis. The association between infertility and a history of PID has long been known, as those with a history of PID have a greater likelihood of tubal disease (Westrom et al., 1992).

Endometriosis

Endometriosis is characterized by the ectopic or abnormal growth of endometrial glands and tissue outside the uterus. Endometriosis can affect any organ within the abdomen and pelvis, but most commonly affects the posterior cul de sac, the lining of the uterus, the lining of the parietal peritoneum, and the ovaries (Agarwal and Subramanian, 2010). Endometrial implants are responsive to hormones of the menstrual cycle and may cause pain and discomfort, and bleeding may result in inflammation, scar tissue, and adhesions formation (Nezhat et al., 2013).

There are several mechanisms by which endometriosis can lead to infertility, including inflammatory changes to free fluid within the pelvis directly impacting egg quality and sperm function, damage to the ovaries by way of endometrioma formation, adhesion and scar tissue formation on the tubes and ovaries which impact their ciliary function, and direct infiltration and damage to the fallopian tubes. Endometriosis has also been shown to impact the endometrium within the uterus, making it less hospitable for embryo implantation, and to release prostaglandins and cytokines that impair sperm motility (Oral et al., 1996).

Endometriosis has various appearances during videolaparoscopic evaluation, appearing as strands or adhesions between organs, dense white fibrous scar tissue, and even as clear fluid filled droplets or vesicles. Lesions can appear colored as black, dark blue, dark red, light red, clear, and white. "Typical" lesions are darker, as the iron from menstrual blood is absorbed in surrounding cells and concentrated. Lesions, especially the clear blister variant, commonly have new and enlarged blood vessels radiating from it, called red flame lesions. Endometriosis can form growths of tissue that can appear as small polyps or deeply infiltrating lesions that penetrate into the organs within the pelvis. The deeply infiltrating lesions appear as dense, fibrous, growths that may be felt when palpated with videolaparoscopic instruments. Scarring and adhesions from endometriosis can be so severe that organs can become entirely fused together. A common example of this is when the posterior aspect of the uterus becomes scarred down onto the sigmoid colon and rectum, completely obliterating the space typically found there, called the posterior cul-de-sac (Nezhat et al., 2013).

Uterine Evaluation

When evaluating the uterus, surgeons examine the size, shape, surface, and contours looking for evidence of asymmetry or pathology. A uterus will change in size over the course of a woman's life. After puberty and before carrying a pregnancy, a healthy uterus is on average 7 cm long, 4 cm across, and 3 cm in depth. During pregnancy, a normal uterus can expand up to 40 cm or more. After a pregnancy, during which the uterus expands to accommodate the growing fetus, the uterus shrinks back down to a slightly larger size of 9 cm long, 5 cm across, and 4 cm in depth (Esmaelzadeh et al., 2004). During videolaparoscopy, an assistant adjusts the uterine manipulator to lift and position the uterus to optimize the surgeon's view. The surface of the uterus is covered by a thin layer of visceral peritoneum which appears smooth and light pink. Patches of red inflammation, white or yellow fibrosis, adhesions, and endometriosis can be readily seen upon the surface of the uterus and help guide a surgeon towards a diagnosis.

If present, two varieties of *uterine fibroids* are visible during videolaparoscopy: subserosal and pedunculated. The subserosal variety may bulge out on the outer surface of the uterus. Pedunculated fibroids are attached only by a narrow stalk to the surface of the uterus. Neither subserosal nor pedunculated fibroids are meaningfully associated with infertility or heavy menstrual bleeding as they do not impact the endometrial cavity.

Adenomyosis is a disease in which the endometrial tissue of the uterus is found to have improperly invaded the muscular layer (myometrium) of the uterus. This invasive endometrial tissue causes the myometrium to expand and negatively impacts the muscle's ability to contract. Adenomyosis is associated with pain, heavy menstrual bleeding and infertility. Definitive diagnosis of adenomyosis requires microscopic evaluation of the myometrium following a uterine biopsy or hysterectomy. That said, non-invasive pre-operative imaging with MRI and transvaginal ultrasound can detect adenomyosis with a sensitivity of 0.79 and 0.74, and specificity of 0.91 and 0.85, respectively (Maheshwari et al., 2012). Furthermore, experienced surgeons may detect evidence of adenomyosis by direct visualization and manipulation of the uterus, such as: being abnormally enlarged, with a flushed, asymmetric, soft, boggy, or sagging appearance.

Cesarean scar defect, also known as niche or *isthmocoele*, is an increasingly common uterine defect at the site of hysterotomy on the anterior wall of the uterus. Improper healing of the cesarean incision leads to thinning of the anterior uterine wall, creating an indentation and fluid-filled pouch. Fibrotic tissue at the niche acts as a valve, leading to painful accumulation of blood within the niche, which can then cause delayed menstruation and lead to abnormal bleeding, pelvic pain, vaginal discharge, and infertility. The defect is most easily seen on ultrasound after the menstrual cycle, when the endometrial lining is very thin and blood has accumulated in the defect. Experienced surgeons may repair a niche hysteroscopically for patients who have completed childbearing, or videolaparoscopically for patients desiring fertility (Nezhat, 2016).

Albeit unlikely to have escaped detection by physical exam or pre-operative imaging, *congenital anomalies* of the uterus can be readily seen during videolaparoscopy. During the development of a female fetus, two independent Müllerian (paramesonephric) ducts fuse within the pelvis of the fetus to form the uterus, fallopian tubes, cervix, and the most inner part of the vagina. If there is a disruption in this process and the Müllerian ducts do not fuse appropriately, a range of anatomic anomalies result, including a septate uterus, bicornuate uterus, unicornuate uterus, or a didelphic uterus (Nezhat et al., 2013).

Ovarian Evaluation

The videolaparoscopic evaluation of infertility proceeds with *inspection of the ovaries*. The ovaries are responsible for maintaining the supply of female sex hormones (estrogen and progesterone) and using them to regulate the menstrual cycle as well as to develop and release an egg each month, a process known as ovulation. Certain forms of hormonal supplements or contraceptives work in part by suppressing the function of the ovaries to prevent ovulation. Hormonal contraceptives can therefore mimic regular menstrual cycles, in the absence of any ovulation. In women who are not receiving these prescribed hormones, a regular menstrual cycle each month serves as an external indication that ovulation is occurring successfully each month.

Ovulatory dysfunction can be identified in reproductive-aged-women who experience infertility with irregular, sporadic, or absent periods. Most forms of ovulatory dysfunction can be diagnosed by obtaining a patient's menstrual history, a few blood tests, ultrasound, and a physical exam.

Healthy ovaries vary widely in appearance and function between women, but also throughout the course of a woman's life as she passes through puberty, each menstrual cycle, and menopause. As eggs develop in the ovaries, they form small pockets of fluid called follicular cysts. Women are born with 1–2 million eggs which decrease over time. By the time she enters puberty, she will have approximately 25% of the eggs she was born with. As a woman's quality and quantity of eggs begins to diminish as she approaches menopause, the ovaries get progressively smaller. *Premature ovarian failure* occurs when a woman's ovaries cease functioning and she undergoes menopause prior to age 40. When viewed videolaparoscopically, the ovaries of a woman with premature ovarian failure will appear atrophied and similar to ovaries of a post-menopausal woman.

Polycystic ovary syndrome or PCOS, is another form of ovulatory dysfunction seen during videolaparoscopy as enlarged, distended ovaries, with a notably bumpy surface filled with small follicular cysts. The cutoff volume threshold between normal and enlarged ovaries is 10 mL or ≥ 12 follicles per ovary (Goodman et al., 2015a,b). In addition, PCOS is associated with impaired glucose metabolism and high level of androgens that can cause excessive body hair and acne. In these patients, abnormal endocrine interactions result in over-production of ovarian functional cysts, with excessive estrogen production and irregular or absent ovulation.

Endometriomas, also known as chocolate cysts, are a common complication of endometriosis as the endometrial tissue invades the ovary and repeatedly bleeds into the ovary, forming a blood-filled cyst. They are called chocolate cysts because, when ruptured, the old blood within the cyst looks like chocolate syrup or pudding. Endometriomas impact a patient's fertility through several mechanisms including: inflammatory damage to the ovaries, pressure or a mass effect within the ovaries, damage to ovarian reserve secondary to surgical treatment of the cysts, and formation of adhesions and scar tissue negatively impacting the ovaries' ability to release an egg (Nezhat et al., 1992).

Fallopian Tube Evaluation

The final component of the videolaparoscopic evaluation for infertility is to assess the *fallopian tubes* for possible "tubal-factor infertility." At their distal end, the tubes have fern-like projections known as fimbriae that collect the egg from one of the ovaries each month. Within the tubes, there are ciliated cells that actively sweep the ovum down into the endometrial cavity of the uterus. Sperm, in contrast, propel themselves up from the vagina, through the cervix, through the endometrial cavity of the uterus, and up through the fallopian tubes. The fallopian tubes, therefore, acts as the meeting place between the ovum and sperm, and is where fertilization take place. For these reasons, open and functional fallopian tubes are critical for a patient's fertility. To test whether the tubes are open, the surgeons perform chromopertubation. *Chromopertubation* is a procedure whereby a dye is instilled through the uterine manipulator, into the uterus, and out through the fallopian tubes in order to assess whether the tubes are open and unobstructed. If the dye is not seen, this can be an indication that there is a physical blockage from fertilization to take place. Following operative treatment of any blockages or pathology within the tube, chromopertubation is repeated to ensure that the fallopian tube had been adequately repaired (Nezhat et al., 2013).

There are several pathologic processes that can negatively impact the structure and function of the fallopian tubes. When this happens, it can lead to infertility directly or because of ensuing ectopic pregnancies. *Ectopic pregnancy*, or the implantation of an embryo at a site other than the endometrial cavity, occurs at a rate of 19.7 cases per 1000 in North America, and it is the leading cause of maternal mortality in the first trimester (Tenore, 2000). Ectopic pregnancies occur 98% of the time within a patient's fallopian tube. While an ectopic pregnancy can happen to anyone, it is more common in patients who have already experienced some form of damage to their tubes, such as pelvic inflammatory disease. There are multiple treatment options for tubal ectopic pregnancies: medical treatment with methotrexate, surgical removal of the affected fallopian tube and ectopic pregnancy together (salpingectomy), or tube-preserving surgical procedures that attempt to remove just the ectopic pregnancy from a tube with the hope of leaving a tube that will remain functional (salpingostomy, salpingotomy, segmental resection with anastomosis, and fimbrial milking) (Song et al., 2016).

Infertile patients with a history of an ectopic pregnancy require consideration both to the cause and consequence of the ectopic pregnancy. The surgeon must assess whether there is visible evidence of damage to the tubes or the surrounding tissue: for example, adhesions or scar tissue from PID, or deeply infiltrating endometriosis (DIE), which can be defined as implants have invaded > 5 mm through the tissue and are associated with severe symptoms (Koninckx et al., 1994). When assessing the outcome of an ectopic, it is not uncommon for patients, especially those with limited health literacy or from developing nations, to not know precisely which operation they received and whether they still have both their tubes. The surgeon will assess which if any of the patient's tubes remain, as well as their structural integrity. In cases where the patient underwent a tube-preserving procedure, special care will be given to determine whether the procedure was potentially successful, or whether scar tissue and strictures have occluded the tube.

When strictures or obstructions form in the fallopian tube, it may result in the tube becoming distended over time with a clear sterile fluid, known as *hydrosalpinx* and may affect one or both fallopian tubes. An affected tube can distend in size up to several centimeters and appear sausage-shaped on videolaparoscopy. Such tubes are inherently blocked and do not permit the transfer of sperm or eggs. When occurring on both tubes, this would result in infertility. In addition, hydrosalpinx decreases the success of in vitro fertilization, with afflicted patients suffering from decreased rates of embryo implantation, pregnancy, and live deliveries, while having increased rates of early pregnancy loss and preterm birth (Camus et al., 1999; Kawwass et al., 2013). Therefore, the affected tube is often surgically removed.

Pelvic inflammatory disease (PID) describes a group of inflammatory gynecological conditions most commonly caused by an infection. As the fallopian tubes serve as a conduit between the endometrial cavity of the uterus and open to the pelvic peritoneum, untreated infections may span from the endometrial cavity of the uterus (endometritis) through the fallopian tubes (salpingitis), to involve the ovaries (oophoritis), the pelvic peritoneum (peritonitis), and even reach as high the liver (perihepatitis). PID can be a life-threatening condition and requires expeditious and broad antibiotic treatment. Unfortunately, relatively mild infections can be asymptomatic and untreated before the infection becomes severe. Upon healing, widespread scarring and adhesions form in the afflicted areas due to the tissue damage caused by the infection, as well as the immune system's response. These scars and adhesions can often be seen during videolaparoscopy and represent a significant source of long-term suffering and chronic pelvic pain. PID related scarring within the fallopian tubes can lead to tubal-factor infertility, hydrosalpinx, and ectopic pregnancies. Risk factors for PID include: age at coitarche, prior history of STI, multiple sexual partners, and barriers to care (Simms et al., 2006; Kreisel et al., 2017).

Cystoscopy and Proctoscopy

Cystoscopy is performed in a similar manner to hysteroscopy, with the cystoscope being passed through the urethra and into the bladder which is subsequently distended with fluid. The cystoscope's fiber-optic lighting and video camera then relay high-definition video of the bladder lumen with its two ureteral orifices to a nearby monitor. The path of the ureters from the kidney to the bladder within the female pelvis puts them at risk of being inadvertently injured when operating in that region. Furthermore, treatment of adhesions between the bladder and the uterus or treatment of lesions near the bladder risk inadvertent perforation of the bladder by the surgical instruments or sutures. Visualization of an intact bladder lumen with strong jets of urine draining into the bladder from each of the two ureteral orifices reassures the surgeon that no such injury had occurred (Nezhat et al., 2013). In addition, cystoscopy affords the surgeons an opportunity to concurrently evaluate the bladder for conditions such as endometriosis of the bladder and interstitial cystitis.

Proctoscopy is performed by passing a lubricated proctoscope through the patient's anus and into their rectum. The proctoscope has a channel and a small balloon of air capable of distending the rectum with air. The surgeon can then visualize directly through a lens on the proctoscope the inside of the patient's rectum and evaluate for any signs of bleeding, puncture, sutures, or injury of the rectum. Simultaneously, another surgeon will be using the laparoscope to examine the exterior surface of the rectum within the pelvis. By covering the rectum within a shallow pool of saline, the videolaparoscopic surgeon can perform a "bubble test" to check for air leaking from the rectum, indicating an injury or incomplete closure. In addition to evaluating for iatrogenic injury, inclusion of the proctoscopy allows for the surgeon to evaluate the patient for endometriosis of the bowel (Nezhat et al., 2013).

Glossary

Androgens Refer to hormones (a type of steroid) that are found in males in much higher concentration than in women and are responsible for many of the male-like features (muscle growth, bears and other male-like hair growth, libido, etc.).

Congenital adrenal hyperplasia Refers to a genetic disorder that affects the ability of the adrenal to produce cortisol and other substances normally.

Polycystic ovary syndrome Is a common genetic trait that presents generally with evidence of hyperandrogenism, ovulatory dysfunction and polycystic ovaries.

Ovulatory dysfunction Refers to abnormal, irregular, infrequent or absent ovulation.

Polycystic ovaries Refer to ovaries that morphologically are larger than usual and contain a larger number of small arrested follicles (cysts) within the ovarian cortex (surface).

Hyperandrogenism Refers to the signs and symptoms of excess male hormone effect in women, including hirsutism, acne, scalp hair loss and high levels of androgens in the blood.

Hirsutism Is a cutaneous sign of hyperandrogenism and defined as excessive male-pattern terminal hair-growth.

Infertility Is a failure of the couple to conceive after one year of regular sexual life.

Introduction

Polycystic ovary syndrome (PCOS) is a disorder affecting 5%–20% of reproductive age women worldwide, depending on diagnostic criteria used (Lizneva et al., 2016a). The main PCOS features include clinical and/or biochemical hyperandrogenism (i.e., hirsutism, acne, androgenic alopecia, hyperandrogenemia), ovulatory dysfunction and polycystic ovarian morphology (PCOM) (i.e., an excessive number of preantral follicles in the ovarian cortex).

The phenotype of PCOS varies across a woman’s lifespan. The clinical presentation of PCOS often starts early in life, and may be associated with premature pubarche in children, early signs of hyperandrogenism (acne, hirsutism) and long-lasting menstrual dysfunction in adolescents. While hyperandrogenic features usually improve in peri-postmenopausal women, the prevalence of metabolic and cardiovascular disorders increases sharply with age, although paradoxically may not increase further than expected for age and body mass after menopause.

The clinical manifestations of PCOS go beyond reproductive signs and symptoms. While polycystic ovaries, hyperandrogenism, and ovulatory dysfunction are considered key features, the majority of affected women also have various degrees of metabolic dysfunction (insulin resistance and secondary hyperinsulinemia). Additional health issues related to PCOS include an increased risk of type 2 diabetes mellitus (T2DM), several pregnancy-related complications (gestational diabetes, meconium aspiration syndrome, preeclampsia), endometrial cancer, and possibly increased risks of cerebrovascular and cardiovascular events, and deep venous thrombosis (Zore et al., 2017).

PCOS Criteria and Phenotypes

PCOS is a syndrome of as yet unknown etiology, although it appears to be a complex genetic trait. Three sets of diagnostic criteria have been proposed to diagnose PCOS (Table 1) (Lizneva et al., 2016a). Currently, there is the general agreement that to be diagnosed with PCOS affected patients should have at least two of three primary features, including chronic anovulation, PCOM, and hyperandrogenism (i.e. the Rotterdam 2003 criteria). Moreover, the 2012 NIH Consensus conference supported the use of Rotterdam criteria, with the caveat that the phenotype(s) of PCOS would also be recorded: Phenotype A—clinical and/or biochemical hyperandrogenism (HA) and oligo-/anovulation (OA) and polycystic ovarian morphology (PCOM) at ultrasound; Phenotype B—HA with OA only; Phenotype C—HA with PCOM only; and Phenotype D—OA with PCOM (Fig. 1).

Table 1 Contemporary diagnostic criteria for PCOS.

NIH (1990)^a Requires both of the following features: 1. Oligo/anovulation (OA) 2. Hyperandrogenism (HA), clinical and/or biochemical
Rotterdam (2003)^a Requires at least two of the following three features: 1. OA 2. HA, clinical and/or biochemical 3. Polycystic ovarian morphology (PCOM)
Androgen Excess & PCOS Society (2006)^a Requires both of the following features: 1. HA, clinical and/or biochemical 2. Ovarian dysfunction, OA and/or PCOM
NIH Consensus (2012)^a Requires at least two of the following three features: 1. OA 2. HA, clinical and/or biochemical 3. PCOM
AND Identification of the specific PCOS phenotypes included: • Phenotype A: HA + OA + PCOM • Phenotype B: HA + OA • Phenotype C: HA + PCOM • Phenotype D: OA + PCOM

Abbreviations: NIH is the US National Institutes of Health; Rotterdam is the 2003 European Society of Human Reproduction and Embryology/American Society for Reproductive Medicine criteria.
^aAll criteria require the exclusion of related or mimicking disorders including, but not limited to, androgen-secreting neoplasms, iatrogenic hyperandrogenism, congenital adrenal hyperplasia, thyroid dysfunction and hyperprolactinemia.

2003 Rotterdam criteria				
2006 AE-PCOS criteria				
1990 US NIH criteria				
	Phenotype A	Phenotype B	Phenotype C	Phenotype D
Hirsutism and/or hyperandrogenemia	+	+	+	-
Anovulatory cycles	+	+	-	+
Polycystic ovarian morphology	+	-	+	+

Fig. 1 PCOS diagnostic criteria and phenotypes. There are four contemporary diagnostic criteria for PCOS. There are also four principal phenotypes of PCOS which differ in their combinations of clinical features, including hyperandrogenism (presence of hirsutism and/or hyperandrogenemia), ovulatory dysfunction, and polycystic ovarian morphology. Phenotypes A and B are most often seen in the clinical setting, because they are the most clinically evident.

PCOS Prevalence

Up to 20% of women of reproductive age have PCOS worldwide ([Lizneva et al., 2016a](#)), although the exact prevalence depends on the diagnostic criteria used: 12%–20% according to the Rotterdam 2003 criteria; 10%–15% when the AE-PCOS 2006 criteria are applied; and 5%–10% when the prevalence is estimated using the NIH 1990 criteria. The higher prevalence of PCOS observed with the Rotterdam and AE-PCOS criteria are related to the inclusion of a greater number of phenotypes of PCOS in these criteria, compared to the NIH 1990 criteria.

PCOS Genetics

PCOS appears to be a complex genetic trait ([Mykhalchenko et al., 2017](#)). Twin studies have demonstrated a high level of heritability (~70%), consistent with the strong influence of genetic factors. The recent genome-wide association studies (GWAS) in several Caucasian and Asian cohorts ([Azziz, 2016](#)) have reported at least 16 robust loci associated with PCOS. Several of these loci are proximate to genes with significant roles regulating gonadotropin secretion and action, ovarian folliculogenesis, insulin secretion and action, weight and energy regulation, and androgen biosynthesis and action.

Mechanisms/Pathophysiology

Potential pathophysiologic mechanisms include primary hypothalamic-pituitary, ovarian, adrenal, and metabolic dysfunctions ([Azziz et al., 2016](#)).

Hypothalamic-Pituitary Dysfunction

Hypothalamically-secreted gonadotropin-releasing hormone (GnRH) is responsible for the secretion of gonadotropins (luteinizing hormone [LH] and follicle-stimulating hormone [FSH]) by the pituitary. In PCOS patients, GnRH appears to be released with increased frequency and amplitude, possibly in part due to hypothalamic resistance to circulating progesterone and/or hypothalamic kisspeptin dysregulation, which leads to increased LH pulse amplitudes, and increased circulating LH and LH/FSH values (more often observed in lean, rather than obese, women with PCOS). This hypothalamic-pituitary dysfunction, together with ovarian resistance to FSH possibly due in part to excess Anti-Müllerian Hormone (AMH) production by the ovary, further increases androgen secretion by the theca cells of ovarian follicles in PCOS. As a result, follicular development is arrested, cycles are anovulatory, and theca cells over-secrete androgens ([Fig. 2](#)).

Ovarian Dysfunction

Much of the ovarian abnormality observed in PCOS may relate to hypothalamic-pituitary dysfunction (see above), it is also possible that intrinsic defects in ovarian function may account for the functional and morphologic gonadal defects seen in the disorder. As

Fig. 2 Scheme of PCOS pathophysiology. Abnormal pulsation of gonadotropin-releasing hormone (GnRH) from hypothalamus, possibly secondary to a reduction in the inhibitory effect of progesterone on GnRH release, leads to increased release of luteinizing hormone (LH) by the pituitary. Although the levels of follicle-stimulating hormone (FSH) are usually normal in patients with PCOS, there may be ovarian follicular resistance to FSH, possibly secondary to increased ovarian concentrations of Anti-Müllerian Hormone (AMH), among other factors. LH hyperproduction, in the face of relative resistance to FSH, leads to excessive secretion of androgens by the ovarian theca, follicular maturation arrest, oligo/anovulation, and the increased accumulation of a greater number of antral follicles in the ovaries, resulting in the characteristic polycystic ovarian morphology (PCOM) and androgen hyperproduction. Adrenocortical dysfunction may contribute modestly to circulating hyperandrogenemia, and metabolic dysfunction results in hyperinsulinemia, which in turn acts on the ovaries to further stimulate androgen secretion by the ovarian theca. *PCOM*, polycystic ovarian morphology; *SHBG*, sex hormone-binding globulin. *Red arrows* indicate inhibitory effect.

noted, anovulation in PCOS is the result of abnormal interactions between LH, FSH, AMH, insulin (see below), insulin-like growth factor 1 (IGF1), and many other substances.

However, and as suggested by the results of recent GWAS, there also may be defects inherent to ovarian follicular function. Dominant follicle maturation occurs irregularly due to relative FSH deficiency and ovarian resistance to FSH, possibly caused by increased levels of AMH. Increased LH stimulates excess androgen production by the theca cells, which in turn promotes excessive primordial follicle accumulation. These arrested primordial follicles individually and as a cohort produce high amounts of AMH, which inhibits aromatase activity, and may also result in FSH resistance, in granulosa cells necessary for further follicular development and maturation (Fig. 3). Thus, even normal levels of FSH in anovulatory PCOS may not be sufficient to overcome the inhibitory effects of AMH.

Increased androgen production in the theca of ovarian follicles in PCOS may also be secondary to the dysregulation of several steroidogenic genes. For example, a recent study observed that *DENND1A* is overexpressed in the theca cells of PCOS, encoding for overactive steroidogenesis in these ovaries (McAllister et al., 2014). Finally, intrinsic defects in insulin action in the ovary may also result in abnormal androgen production. In general, these mechanisms result in ovarian hyperandrogenism, ovulatory dysfunction, and circulating hyperandrogenemia and hyperestrogenemia (secondary to the peripheral conversion of androgens to estrogens).

Fig. 3 Ovarian follicular arrest in PCOS. In PCOS ovarian follicular maturation is generally arrested at the early antral stage. *Green lines* indicate stimulation, *red lines* indicate inhibition, and *blue lines* indicate synthesis.

Adrenal Dysfunction

Approximately one-third of patients with PCOS demonstrate evidence of excess adrenal androgen production, principally reflected in increased circulating levels of dehydroepiandrosterone (DHEA) sulfate (DHEAS) ([Goodarzi et al., 2015](#)). These patients demonstrate increased responsivity, but not increased sensitivity, of adrenal androgens to adrenocortical releasing hormone (ACTH) stimulation. However, they do not demonstrate a change in ACTH sensitivity to corticotrophic releasing hormone (CRH) stimulation. Steroidogenically PCOS subjects demonstrate enhanced Δ^5 17–20 lyase activity, reflecting apparent intrinsic cytochrome P450c17 α (CYP17) dysfunction. Overall, however, adrenocortical excess plays a limited role in the pathophysiology of PCOS due to the relative weakness of androstenedione and DHEA, the principal androgens secreted by the adrenal cortex.

Metabolic Dysfunction

Patients with PCOS demonstrate reduced sensitivity to the glucose and lipid, but possibly not the anabolic, effects of insulin. In compensation, patients with PCOS secrete increased levels of insulin, resulting in hyperinsulinemia ([Diamanti-Kandarakis & Dunaif, 2012](#)). Hyperinsulinemia in PCOS can also be exacerbated by decreased hepatic insulin extraction. Excess insulin in PCOS stimulates increased androgen production by the ovarian theca cells and decreased androgen binding in the circulation by inhibiting the hepatic production of sex hormone-binding globulin (SHBG).

We should note that in normal states decreases in insulin sensitivity result in increases in insulin secretion, a constant hyperbolic relationship which reflects the ability of pancreatic islet beta cells to compensate for the insulin resistance. This relationship between insulin secretion and insulin resistance is expressed by the Disposition Index (DI). However, in PCOS despite the prevalent hyperinsulinemia, the insulin secretory response for the degree of insulin resistance is inadequate, resulting in a decreased DI compared with age and body mass index (BMI)-matched controls. Overall, these data indicate that despite the level of hyperinsulinemia observed in PCOS, these patients actually demonstrate relative beta-cell insufficiency.

The molecular pathophysiology of the insulin resistance in PCOS differs from that observed in T2DM or obesity. The molecular defects in insulin action observed vary somewhat according to the tissues studies, although in general there are few defects observed in the mitogenic, as opposed to the glucose transport, insulin signaling cascade. Defects in insulin action have been observed in various tissues including skin fibroblasts, ovary, muscle and myocytes, and adipose tissue and adipocytes ([Diamanti-Kandarakis & Dunaif, 2012](#); [Corbould et al., 2006](#); [Chen et al., 2013](#)). In adipocytes of PCOS inflammatory cytokines (e.g. TNF- α) appear to have a stronger inhibitory effect on insulin-mediated glucose transport and adiponectin (an insulin-sensitizing adipokine) secretion, compared to controls ([Chazenbalk et al., 2010](#)). Further, adipocytes in PCOS demonstrate impaired Glucose Transporter 4 (GLUT4) expression (10).

Clinical Signs

Dermatologic Abnormalities

Hirsutism is observed in at least two-third of White and Black women with PCOS. Hirsutism is characterized by the presence of terminal (thick, coarse and pigmented) hairs in androgen-dependent areas, such as the upper lip, neck and chin, upper and lower abdomen, upper and lower back, buttocks and thighs, and upper arms ([Azziz et al., 2016](#); [Lizneva et al., 2016b](#)). The development of hirsutism in PCOS occurs gradually, which allows it to be clinically differentiated from hirsutism associated with androgen-secreting neoplasms, where the onset of hair growth is usually rapid and more severe, and others signs of virilization are present (e.g. clitoromegaly).

Additionally, 15%–25% of patients with PCOS demonstrate acne. While acne is considered to be a common finding in adolescence, if acne is severe, resistant to treatment, persists after puberty, or exacerbates in the mid-20s, evaluation for hyperandrogenism may be indicated. Finally, some women with PCOS and other hyperandrogenic disorders demonstrate androgenic alopecia (a diffuse thinning of the hair in the sagittal area of the scalp) and in more severe cases demonstrate frank male-like pattern balding.

Menstrual Abnormalities

The vast majority of patients with PCOS demonstrate some degree of menstrual dysfunction ([Azziz et al., 2009](#)) reflecting the underlying ovulatory dysfunction, including oligomenorrhea, amenorrhea and occasionally polymenorrhea. However, some patients may also present with apparent eumenorrhea. In one study, 40% of subjects with hirsutism and apparent eumenorrhea demonstrated underlying ovulatory dysfunction.

Polycystic Ovaries

At least 80% of PCOS subjects demonstrate PCOM, characterized by increased ovarian volume (i.e. generally > 10 mL) and/or increased antral follicle count (AFC, i.e. generally > 12 to > 20 follicles 2–9 mm in diameter). PCOM is usually detected by ultrasonography, and as the technology has improved so has the ability to detect and differentiate small follicles, suggesting the need to increase the cut-off value for AFC for diagnosing PCOM ([Dewailly et al., 2014](#)).

Associated Morbidities

Associated morbidities include increased risks for subfertility, obstetrical complications, obesity, metabolic dysfunction, vascular complications, malignancies, and mood disorders and psychosexual dysfunction ([Zore et al., 2017](#)).

Subfertility

Women with PCOS have impaired fertility primarily due to oligo-anovulation. Infertility is 15 times prevalent in PCOS patients, regardless of BMI, compared to controls.

Obstetrical Complications

Pregnancies in PCOS patients have a significantly higher rate of complications including pre-eclampsia, very preterm delivery (< 32 weeks of gestation), gestational diabetes, fetal macrosomia, and signs of fetal distress (e.g. meconium aspiration syndrome, low Apgar scores) ([Roos et al., 2011](#); [Wang et al., 2013](#)).

Overweightness and Obesity

Recent clinical studies demonstrated a higher prevalence of obesity in PCOS women referred for clinical care, whereas the BMI distribution of PCOS women detected in screening studies in the general population are not much different than that observed in non-affected women in the same population ([Lizneva et al., 2016c](#)). Interestingly, there are no significant differences in the prevalence of PCOS in different countries, despite significant variations in mean population BMI and obesity incidence ([Lizneva et al., 2016a](#)). No association between variants in genes known to be associated with obesity and PCOS has been found ([Cai et al., 2014](#)). These data further support the notion that the relationship of obesity and PCOS is tenuous at best.

Metabolic Dysfunction and Glucose Intolerance

Hyperinsulinemia (both basal and glucose-stimulated) is observed in the majority of PCOS patients. Premenopausal women with PCOS have higher odds for impaired glucose tolerance (IGT), T2DM, and the metabolic syndrome than age- and BMI-matched controls. Approximately 2% of PCOS women progress from normoglycemic status to T2DM yearly.

Cardiovascular and Cerebrovascular Complications

The prevalence of cardiovascular markers of disease is higher in women with PCOS. These include coronary and aortic calcification, aortic stenosis (based on coronary angiography) and a thicker intimal layer of the carotid wall compared with controls. However, while the risk of cerebrovascular complications appears to be increased in PCOS, it is less clear whether the risk of cardiovascular events is actually increased in the disorder. In addition, the odds of deep vein thrombosis (DVT) are at least 1.5 fold higher in untreated women with PCOS vs. BMI-matched controls, and even higher (2-fold greater) in PCOS patients taking oral contraceptive pills (OCPs).

Malignancies

Taking into account the coexistence of anovulation, hyperestrogenemia, and hyperinsulinemia in PCOS, the risk of endometrial cancer is higher in women with PCOS (approximately 2.7 fold greater). The risk of ovarian cancer may also be increased, although data is mixed. No significant increase in the risk of breast cancer in PCOS patients compared with controls has been observed ([Zore et al., 2017](#); [Azziz et al., 2016](#)).

Mood Disorders and Psychosexual Dysfunction

Recent studies report a higher incidence and severity of mood disorders (depression, anxiety) and psycho-sexual dysfunction, in women with PCOS compared to non-PCOS patients. The increased risk is independent of BMI and PCOS phenotype, but correlated with the degree of insulin resistance ([Cinar et al., 2011](#)).

Diagnosis

All criteria used today include assessments for hyperandrogenism, ovulatory dysfunction and ovarian morphology ([Table 1](#)). The evaluation of PCOS patients should include assessment for hyperandrogenism (hirsutism scoring, evaluation for acne and alopecia, monitoring of circulating androgen levels), ovulatory function (detailed menstrual history and luteal progesterone level testing in eumenorrheic hirsute women), and the evaluation of ovarian morphology for PCOM by ultrasonography, preferably transvaginal.

Hirsutism is assessed using a visual scoring method. A score of >6 on a modified Ferriman–Gallwey (mFG) scale defines the presence of hirsutism, although larger populational studies suggest that mFG values as low as 3 may be abnormal. Girls with severe or persistent acne have an increased probability of having PCOS. Biochemically, the measurement of free testosterone is superior to total testosterone alone for the detection of hyperandrogenism. Measurement of testosterone is innately difficult and most commercial or platform assays are insensitive in the female range; consequently the optimum method for assessing total testosterone, also used to calculate free testosterone, is mass spectrometry.

Chronic anovulation is assumed in individuals with oligo-amenorrhea, i.e. prolonged (>35 – 45 days) menstrual cycle or <8 to 10 cycles per year. In such cases, no further testing for anovulation is required. Alternatively, a history of apparent ‘eumenorrhea’ in a patient with other signs of hyperandrogenism (e.g. hirsutism) suggests the need for further assessment of ovulatory status. A mid-luteal progesterone (days 22 to 24 of the cycle) can be used to confirm ovulation.

According to the Rotterdam criteria, PCOM is determined by the presence of 12 or more antral follicles (i.e. measuring 2 to 9 mm in diameter) in the ovary and/or an increase in ovarian volume (>10 mL). However, because more contemporary ultrasound probes have a much greater sensitivity, threshold counts for antral follicles may be as high as 25 (Dewailly et al., 2014). In the absence of accurate ultrasonography AMH values >4.5 ng/mL may be used as a substitute for PCOM, although this remains to be confirmed (Dewailly et al., 2014).

All PCOS criteria used today (Table 1) require the exclusion of mimicking/similar disorders, including but not limited to thyroid disorders and hyperprolactinemia for oligo-anovulation, and androgen-secreting tumors, congenital adrenal hyperplasia, and iatrogenic causes for hyperandrogenism. For instance, nonclassic 21-hydroxylase (CYP21A) deficiency may have the same clinical presentation as PCOS (hyperandrogenism, anovulation, and PCOM), and only a circulating 17-hydroxyprogesterone (17-OHP) can be used to discriminate between the disorders (Pall et al., 2010). Post-stimulation 17-OHP values >10 ng/mL confirm the diagnosis, whereas 17-OHP levels between 2 and 10 ng/mL require an acute ACTH stimulation test for diagnosis (Lizneva et al., 2016b).

Once the diagnosis of PCOS is established, patients should be assessed for glucose intolerance, dyslipidemia, and mood disorders. An oral glucose tolerance test (oGTT) is the preferred method for detecting glucose intolerance or T2DM, and should be repeated every 2 to 3 years, depending on BMI and family history of T2DM, and yearly in women with impaired glucose tolerance as the rates of progression from normal to IGT and T2DM have been reported to be between 5% and 15% within 3 years (Salley et al., 2007).

Every newly diagnosed PCOS patient should also be evaluated for cardiovascular disease and metabolic syndrome risk factors (BMI, age, smoking, family history, lipid profile, liver function tests, high blood pressure, etc.). Further assessment should be considered on an individual basis.

Finally, in PCOS women with a long-standing of anovulation and no endometrial protection, endometrial hyperplasia/cancer should be excluded by ultrasonography and endometrial sampling.

Screening for PCOS in Childhood and Adolescence

Daughters and sisters of women affected by PCOS have a higher chance of developing the disorder (Mykhalchenko et al., 2017); therefore, early screening should be recommended for all first degree relatives of affected patients. Initial treatment with the insulin-sensitizer metformin (see below) may reduce progression to PCOS in girls, at least those with low birthweight and precocious pubarche.

Acne, hyperinsulinemia, and anovulatory cycles are often seen during the pubertal transition. However, irregular menstruation might require medical attention if it persists more than three years after menarche, generally after age 15 years old. In addition, the threshold for defining oligomenorrhea is somewhat higher during in adolescence (i.e. a menstrual cycle length >40 days is considered abnormal) compared to adult women (i.e. cycles >35 days in length are considered abnormal).

The current recommended approach to detecting PCOS in adolescent girls at risk for the disorder is to wait for 2–3 years after menarche before starting vigorous evaluations, unless signs and symptoms mandate an evaluation sooner, and to not finalize the diagnosis unless the clinical picture is unambiguous (Witchel et al., 2015). Early confirmation of the diagnosis helps to reduce the long-term sequelae of hirsutism, acne and alopecia and may reduce the probability of later complications, such as T2DM and endometrial cancer.

Management

An individualized approach should be used for every patient with PCOS as this disorder is heterogeneous, complex, multifactorial and life-long (Azziz et al., 2016; Lizneva et al., 2016b).

Management of PCOS-Associated Obesity

Lifestyle modification

First-line treatment in obese or overweight patients with PCOS is lifestyle modification, which alone may significantly improve ovulatory, mood, fertility and metabolic dysfunction. Even a minimal reduction ($>5\%$) of body weight in a PCOS woman with

increased BMI significantly improves metabolic dysfunction and ovulation. Weight loss achieved by a high-protein diet is well tolerated and improves satiety, but there is still no specific diet recommended for PCOS women that has been studied long-term. Physical activity, even high intensive, usually has a limited effect on weight loss in PCOS patients. However, if performed for at least 30 min per day five times per week, physical exercise may improve insulin resistance and reduce cardiovascular risk.

Medical therapy

Medical treatment is available for weight reduction. Few of these medications have been studied in PCOS. Orlistat, which inhibits lipase in the intestine, has a positive effect on weight reduction in women with PCOS.

Bariatric surgery

Bariatric surgery is another option for obese women with PCOS, reserved for those individuals with morbid obesity (BMI > 40 kg/m²) and for women with BMI > 35 kg/m² who have other health issues. It is highly effective as it improves not only body weight, but also signs of PCOS, by 46% to 7%, with a mean weight loss of about 60% (Skubleny et al., 2016).

Management of Metabolic Dysfunction and Dyslipidemia

Insulin sensitizers

In patients with significant insulin resistance/hyperinsulinemia and/or at increased risk for glucose intolerance (e.g. demonstrating elevated levels of insulin and/or glucose intolerance during an oGTT, a strong family history of glucose intolerance, acanthosis nigricans, etc.) improvement in insulin sensitivity should be considered, either through weight loss (see above) or the use of insulin sensitizers. If lifestyle modification is not sufficient in an obese patient with PCOS, or the patient is not obese (considering that between 40% and 60% of PCOS women may not be obese) additional medical measures should be considered for long-term improvement in insulin sensitivity. Metformin (a biguanide) is commonly used to manage glucose intolerance and T2DM, as it suppresses hepatic glucose synthesis and improves insulin sensitivity peripherally. In PCOS it also reduces insulin-dependent androgen synthesis, and improves menstrual function and fertility. When combined with lifestyle modification, it facilitates weight loss in obese women with PCOS, although metformin alone has no significant impact on BMI in obese women and does not improve fasting glucose and lipid levels.

Thiazolidinediones have a stronger effect on insulin resistance and fasting insulin levels, but are not as efficient in normalizing excess weight and triglyceride levels. Because of possible serious side effects, they are not routinely recommended for use in PCOS, although may be reserved for those patients with serious and severe degrees of insulin resistance.

Inositol isomers (di-*chiro*-inositol and/or myo-inositol) have insulin-mimetic properties because they take act as secondary messengers in the insulin signaling cascade, which explains their effectiveness in reducing post-prandial glucose levels. They may also significantly improve insulin resistance and menstrual regularity in PCOS, although di-*chiro*-inositol alone was not found to be as effective as expected. A combination of the two isomers may be more effective. The exact dosing of these substances is unclear, and their benefit in PCOS management remains to be investigated.

Acarbose suppresses α -glucosidase and is known to improve lipid levels in PCOS patients, but the effect on BMI in these subjects is unclear.

Statins

Statins (HMG-CoA reductase inhibitors) are effective in normalizing dyslipidemia in PCOS, reducing the circulating levels of total cholesterol and triglycerides. The beneficial effect of statins on lipids in PCOS may be further augmented if used together with metformin, but this combination lessens the beneficial effect of metformin on insulin resistance. The safety of statins in pregnancy is unclear, and these drugs should be discontinued before conception.

Management of Hyperandrogenic Signs and Symptoms

Combination hormonal contraceptives

Combination OCPs are first-line treatment for menstrual irregularity in women with PCOS who are not seeking pregnancy. They inhibit ovarian androgen production by suppressing gonadotropin secretion, thus improving hirsutism and acne, and normalize menstrual cyclicity. Further, the estrogenic component of the OCP increases hepatic production of SHBG. This effect is not seen with transdermal contraceptives. The progestin component of OCPs may also directly suppress the synthesis of ovarian androgens. OCPs also protect women with PCOS against their higher risks of endometrial hyperplasia and cancer (see below). Prior to administering OCPs patients should be screened for contraindications to their usage. On occasion, reduction in androgen production can be achieved with continuous progestogens or rarely long-acting GnRH analogues.

Antiandrogens

Direct androgen receptor antagonists in general use in PCOS patients include spironolactone (SPA), flutamide (FLUT), and the progestogen, cyproterone acetate (CPA). SPA is the most commonly used androgen inhibitor in the United States, while CPA and FLUT are more widely used elsewhere. SPA is effective in the management of hirsutism (dosage is 25–100 mg bid). As it is also a diuretic, acting as an aldosterone inhibitor, patients may demonstrate polyuria, hypotension and even syncope. Rarely

will patients develop hyperkalemia and serum potassium levels may be monitored at regular intervals. Other side effects include dyspepsia, excess sensitivity to sun, and atopic reactions. FLUT (used in doses of 50–100 mg/day) has less side-effects than SPA, although may result in greenish urine. More importantly, and although quite rare, PCOS and other patients have been reported to suffer from sudden fulminant hepatic failure and death while on FLUT therapy. Thus FLUT is not recommended as first line therapy for PCOS-associated hyperandrogenism and patients taking FLUT should have their liver function tests monitored before and at regular intervals during treatment. CPA is a progestogen and is frequently included in a combination OCP in doses of 2 mg/day. However, this dosage provides limited antiandrogenic effect, and supplemental CPA in doses of 10–30 mg/day should be considered in patients with significant clinical hyperandrogenism.

5 α -reductase inhibitors (e.g. finasteride) antagonize the effect of androgens by inhibiting the conversion of testosterone to its more potent metabolite, dihydrotestosterone (DHT). It is used in a daily dose of 5 mg and has little side-effects.

All antiandrogens are considered potentially teratogenic, particularly to a male fetus, where underdevelopment of the genitalia may occur, and may also be associated with a slight decrease in libido and muscle strength. Combining antiandrogens with OCPs provides contraceptive protection against pregnancy and potentiates their respective effect on hyperandrogenism. In general, improvements in androgen-associated acne may be evident within 2–3 months and improvements in hirsutism within 6 months of treatment, while improvements in androgenic alopecia are much less consistent and will take longer.

Eflornithine hydrochloride

A topical eflornithine hydrochloride solution irreversibly suppresses ornithine decarboxylase in hair follicles and can be used for the local treatment of excessive facial hair.

Cosmetic treatments

Inhibition of androgen synthesis and their peripheral action helps to prevent progression of skin changes in PCOS (hirsutism, acne, androgenic alopecia), and may ameliorate them over time. However, the addition of cosmetic measures should be considered to both accelerate the process and treat signs that do not regress with medical therapy alone. Hirsutism may be treated temporarily by shaving, depilation, or waxing. More permanent destruction of the offending hair follicles may be achieved with laser therapy and, more effectively, electrolysis. Acne can be managed with various medications including retinoids and antibacterials. Topical minoxidil and hair transplantation can be used for androgenic alopecia.

Endometrial Protection

Chronic anovulation and hyperestrogenism place women with PCOS at greater risk for endometrial hyperplasia and cancer ([Zore et al., 2017](#)), and dysfunctional uterine bleeding, which in turn can result in iron deficiency anemia. To prevent these complications a combination hormonal contraceptive or cyclic progestogen should be used.

Treatment for Subfertility

Not all patients with PCOS are ‘infertile’ as PCOS patients do ovulation, albeit at a third of the rate of normal subjects. Further, satisfaction with ‘fertility’ depends on the age of the patient, how long she has had unprotected intercourse and her reproductive aspirations. When managing the subfertility of PCOS patients it is important to strive to achieve monofollicular ovulation in this group of patients to reduce the inherent risks of multiple births, and taking into account their increased risk of pregnancy-associated complications, including pre-eclampsia, gestational diabetes, preterm labor, and fetal distress. Prior to planned conception, women with PCOS should be counseled about the risks and success rates of future pregnancy, and encourage lifestyle modification. Screening for coexisting conditions should also be performed, including glucose intolerance and insulin resistance.

Monofollicular ovulation is commonly achieved by the use of clomiphene citrate, which competes with estrogen for binding in the hypothalamus, thus increasing production of gonadotropins. More recently, the aromatase inhibitor letrozole has proven superior to clomiphene, since it has a better probability of live births (40%–50%) and is more effective in obese PCOS women. Multiple pregnancies are observed in up to 8% of patents when these drugs are used for ovulation induction. Metformin has a modest beneficial effect on fertility but can increase the effectiveness of clomiphene citrate in some cases ([Legro, 2016](#)). Overall, patients should undergo 5 or 6 cycles of ovulation induction with these medications, assuming the patient is ovulatory, before pursuing other fertility treatments.

Gonadotropins, either an LH and FSH combination, or FSH alone, are considered second-line treatment. Administration and response should be monitored carefully to minimize the risk of multiple pregnancies (<5%) and ovarian hyperstimulation syndrome (OHSS). A low dose regimen is usually prescribed. Gonadotropin therapy is more effective in achieving pregnancy than clomiphene or letrozole, but has greater associated risks and costs.

Surgical approaches have also been used to improve ovulatory function and possibly decrease ovarian androgen production, in patients who fail clomiphene and/or letrozole. The original procedure was to perform an ovarian wedge resection (OWR), where a wedge of tissue is removed from the ovary. This has the effect of decreasing the amount of stromal-thecal tissue and reducing intrinsic androgen production with a significant positive effect on hyperandrogenism and ovulation, at least temporarily. Patients may develop adhesions and diminished ovarian reserve as long-term complications of OWR. Although OWR today can be performed laparoscopically and with preservation of a fair amount of the ovarian cortex, the preferred surgical method of treating

PCOS currently is laparoscopic ovarian drilling (LOD). The criteria for using LOD for ovulation induction is clomiphene resistance, increased LH, no possibility or contraindication to using gonadotropins, and the presence of other indications for laparoscopy. LOD is better tolerated and results in fewer adhesions and less risk of premature ovarian failure than OWR.

In vitro fertilization (IVF) is considered third line treatment for PCOS-associated infertility. The pregnancy rates with IVF are similar in patients with PCOS vs. those with other causes of infertility. In countries where multiple embryo transfers are allowed, the risk of multiple pregnancies may reach 30%. When single embryo transfers are performed, the risk of multiple pregnancies is significantly lower compared to ovulation induction with gonadotropins.

To minimize the risks of multiple pregnancies and OHSS in PCOS, various modifications to IVF have been introduced. In vitro maturation (IVM) is one example, as is cryopreservation of embryos and transfer at a later date, after the ovarian stimulation has receded. Recent studies have indicated that frozen-embryo transfers in PCOS women are associated with a higher probability of a live birth. Alternatively, pregnancy rates with IVM in PCOS is generally inferior to those achieved with IVF (Siristatidis et al., 2013).

Improvement in Quality of Life (QOL)

Quality of life (QOL) is a complex concept including many components (mental, physical, emotional), all of which are compromised in PCOS women. Obesity, dermatologic symptoms (hirsutism, acne, androgenic alopecia), irregular menses, subfertility, and psycho-sexual dysfunction all negatively affect QOL in these patients. The PCOSQ questionnaire is PCOS-specific and includes five domains of questions that are able to assess QOL (Guyatt et al., 2004). Women with PCOS consistently report a reduction in QOL scores vs. controls, as well as poorer body image.

A recent randomized trial indicated that the QOL of women with PCOS was improved (i.e. better PCOSQ scores) in response to lifestyle modifications in combination with OCPs. However, when metformin was added to their treatment, no further QOL improvement occurred. While OCPs improve dermatologic symptoms and menstrual abnormalities, they do not appear to affect mood disorders. Assessment and management of mood disorders in PCOS women should follow standard practice, and should not be ignored just because the patient may have PCOS.

Hyperandrogenemia

Neil Chappell and Amy Schutt, Texas Children's Hospital, Houston, TX, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Hyperandrogenemia (HA) describes the condition of a patient with increased production of a group of steroid hormones known as androgens, from the Greek prefix "andro" meaning "man." While these hormones play a central role in male physiology, they are also present to a lesser degree in females, with the most predominant androgens including testosterone, dihydrotestosterone (DHT), androstenedione, dehydroepiandrosterone (DHEA), and dehydroepiandrosterone sulfate (DHEA-S). In women, androgens are synthesized by two endocrine organs, the ovaries and the adrenal glands, with some androgens also produced peripherally in the skin, subcutaneous tissues, and liver. The ovaries and adrenal glands both synthesize testosterone, androstenedione and DHT, while the adrenal glands are responsible for all DHEA-S production. The overall incidence of HA in women is approximately 5%–10%, with polycystic ovarian syndrome (PCOS) accounting for approximately 80% of cases. In general, HA may also be caused by exogenous medications, endogenous neoplasms, or via the nonneoplastic overproduction of androgens. Clinical signs of HA include acne, abnormal hair growth (hirsutism), and male pattern baldness (alopecia) (Azziz et al., 2004; Fritz and Speroff, 2011; Lizneva et al., 2016). Other signs of HA may also be present, including irregular menstrual cycles, virilization (deepening voice, enlarging clitoris, breast atrophy), or insulin resistance.

The steroid biosynthesis pathway and the enzymes that produce these hormones are the same in both men and women (Fig. 1, steroid hormone biosynthesis). However, there are distinct gender and tissue specific differences in the amount and activity of each of these enzymes in the body, and this balance regulates the predominant hormones produced at any one location at any given time. There are additional changes in the steroid biosynthesis pathway during pregnancy, both within the fetal and placental compartments, that can affect exposure to androgens. A complete understanding of the etiology of hyperandrogenemia in a patient requires a full appreciation of this pathway, and thus warrants further discussion in this article.

Fig. 1 Steroid hormone biosynthesis.

All steroid hormones that are synthesized via the steroid biosynthesis pathway are formed from the precursor cholesterol, which is transported into the cell by the enzyme StAR (steroid acute regulatory protein). Once inside the cell, cholesterol is cleaved by the side chain cleavage enzyme p450_{scc} into pregnenolone. Pregnenolone is then shuttled to one of several end products, depending on the tissue type and environmental cues from the body: aldosterone, cortisol, testosterone, or estradiol. Additionally, all of the intermediary hormone products formed between pregnenolone and the final end products also have endocrinologic profiles and functions that must not be forgotten. Of note, the adrenal gland has a special enzyme known as a sulfurase, which allows it to convert some DHEA into DHEA-S, making this hormone a unique marker of adrenal production.

The adrenal cortex has three layers—the zona glomerulosa, the zona fasciculata, and the zona reticularis—where aldosterone, cortisol, and androgens are produced, respectively. In the cortex of the adrenal gland, there is significant expression of 21 hydroxylase and 11 beta hydroxylase, to allow for the production of hormones such as aldosterone and cortisol along with a smaller amount of DHEA (Fritz and Speroff, 2011). The ovary, however, has more 17,20-desmolase and 17-beta-hydroxydehydrogenase activity which shunts the steroid pathway toward more androstenedione and estradiol production. The overarching concept in steroid hormone production lies in the regulation of the expression and activity of these steroid producing enzymes which allows for the preferential shunting of steroids to different end hormone products, depending on the tissue site and the body's needs at a given time.

Admittedly, the ovary is perhaps more complicated, and this added complexity is important to understand and appreciate the pathology of ovarian HA. One of the main functions of the ovary is to produce estradiol, the main form of estrogen in the female endocrine system. This is produced in two major steps. First, a specific cell type known as the theca cell produces androstenedione, which is then shuttled to another cell type called the granulosa cell. There, it undergoes a final change by the enzyme aromatase to produce the end product estradiol. This “two cell theory” is a foundational concept when considering ovarian physiology, and will be discussed in detail in the following sections.

With an understanding of steroid hormone production and an appreciation for the vast diversity of action and expression among organ sites, it is also germane to discuss the manner in which production of these hormones is stimulated. Both the ovary and the adrenal gland receive signals from the brain, specifically the pituitary gland, which is in turn regulated by the hypothalamus just superior to the pituitary gland and connected by a fenestrated collection of capillaries known as the hypophyseal portal system. This delicate vascular network allows rapid and frequent communication from the hypothalamus to the pituitary, resulting in tightly regulated control of downstream endocrine organs. The hypothalamic-pituitary connections to the ovary and the adrenal gland are known as the hypothalamic-pituitary-ovarian axis (HPO) and the hypothalamic-pituitary-adrenal axis (HPA), respectively. These axes constitute important endocrine feedback systems that allow for the homeostatic regulation of hormone production. Indeed, the hypothalamic-pituitary stimuli are sensitive to steroid products from the adrenal gland and the ovary, decreasing upstream signals from the brain in response to increasing levels of hormones in the blood through a process known as “negative feedback.”

Specifically, the HPA axis consists of the hypothalamic release of corticotropin-releasing hormone (CRH) to trigger release of adrenocorticotrophic releasing hormone (ACTH) from the pituitary, resulting in the adrenal production of steroid hormones, which then feed back to the hypothalamus and pituitary to downregulate both CRH and ACTH. For the HPO axis, due to the two cell theory, it is slightly more complicated. First, the hypothalamus releases gonadotropin releasing hormone (GnRH) with a specific amplitude and frequency that occurs in part due to stimulation of the GnRH neuron by kisspeptin/GPR54 signaling. GnRH release results in the pituitary secretion of gonadotropins—luteinizing hormone (LH) and follicle stimulating hormone (FSH). The amplitude and frequency of the GnRH signal dictates the ratio of LH to FSH, and this ultimately drives the delicate balance of ovarian steroidogenesis. This in turn controls ovarian recruitment and maturation of an egg (folliculogenesis), ovulation, and the overall cyclicity of the menstrual cycle. Any aberration in kisspeptin, GnRH, LH, and FSH signaling, or the process by which the ovary forms steroid hormones can result in abnormal levels of androgenic precursors, and can subsequently result in pathologic conditions such as HA.

Finally, to fully appreciate the mechanisms responsible for the causes of HA, one must also recognize that each steroid hormone will have different effects, as each will have varying degrees of androgenic actions. Simply put, the amount and type of hormone that is overproduced in a given patient will dictate the severity of the symptoms. For example, DHT has two to three times greater affinity for the androgen receptor compared to testosterone, and additionally has a longer half-life than testosterone, and therefore DHT is a more potent androgen between the two. Similarly, testosterone is a more potent androgen than DHEA. Thus, a patient that is overproducing DHT will likely have a more severe form of HA than a patient that has a slightly elevated DHEA level.

The purpose of this article is to address the various causes of HA in the female population. In order to address this topic in an organized manner, we have divided up the differential diagnosis by age, specifically addressing the population prior to onset of puberty, after puberty, and after menopause.

Medical Causes of Hyperandrogenemia

Prepubertal

Girls that have yet to undergo puberty represent a population in which the ovary is comparatively quiescent, and since this site of androgen production is underactive, overt HA is rare (Catteau-Jonard et al., 2012). Nevertheless, it is becoming increasingly more common to see HA in this cohort due to pathology such as PCOS. As this particular disease is more appropriately covered in the postpubertal section, discussions on the differential diagnosis of HA in prepubertal females will be limited to physiologic HA, congenital adrenal hyperplasia (CAH), and tumors.

Physiologic hyperandrogenism of puberty

As a female enters puberty, at least in part due to direct stimulation from kisspeptin/GPR54 signaling in the brain, the hypothalamic-pituitary axis awakens by initiating small pulses of GnRH from the hypothalamus, which preferentially results in small levels of LH pulses as well. Therefore, there is a higher preponderance of LH to FSH during the initial few months of pubertal awakening which results in more theca cell stimulation and more ovarian androgen production in the predominant form of androstenedione. This is known as physiologic hyperandrogenism of puberty and is historically transient (Catteau-Jonard et al., 2012). FSH production will soon follow these LH pulses as the HPO axis matures and GnRH pulsatility becomes more physiologically consistent with a postpubertal pattern. In turn, estradiol production increases, ultimately resulting in the establishment of a consistent negative feedback cycle on the hypothalamus and pituitary and therefore the establishment of regular, cyclic menses.

Congenital adrenal hyperplasia

Congenital adrenal hyperplasia is a condition that encompasses several enzymatic defects in the steroid pathway from various mutations, usually autosomal recessive in inheritance. Collectively, these conditions are rare, and the resulting phenotype depends both on which enzyme is affected as well as the amount of impairment that the mutation conveys (Fritz and Speroff, 2011). In essence, the enzyme defect results in decreased production of either cortisol, aldosterone, or both from the adrenal gland and the low levels of these hormones results in a compensatory increase in ACTH from the pituitary (due to decreased negative feedback), which then drives more adrenal steroid production. As this does not fix the inherent enzymatic defect, this results in increased shuttling of upstream steroid precursors to more androgenic products, resulting in HA.

The majority of the defects are recognized early in life, and are treated with supplementation of any steroid products that are rendered deficient. The exception is also the most common of these conditions, known as nonclassical CAH, which involves a subtype of mutations in a particular enzyme in the steroid pathway called 21-hydroxylase. Nonclassical CAH presents later in life, around the time of puberty as ovarian steroidogenesis increases with increasing gonadotropin expression in the HPO axis. A hallmark of nonclassical CAH is the significant increase in the steroid immediately upstream of 21-hydroxylase, known as 17-hydroxyprogesterone (17-OHP). Diagnosis of nonclassical CAH from a mutation in 21-hydroxylase is suspected if a morning 17-OHP, preferably in the follicular phase, is $> 200 \text{ ng mL}^{-1}$. Table 1 provides a summary of the enzymatic defects that can cause CAH along with their subtypes and clinical manifestations.

Table 1 Congenital adrenal hyperplasia: summary of the different enzymatic defects seen in congenital adrenal hyperplasia, with details regarding subtypes and their clinical manifestations

<i>Congenital adrenal hyperplasia</i>	<i>Facts</i>	<i>Forms/types</i>	<i>Manifestations</i>
21 hydroxylase deficiency	• 90% of all cases • Autosomal recessive • Chromosome 6	Severe form	• Cortisol and aldosterone deficient • Ambiguous genitalia
		Classical form	• Compensatory ACTH enough to provide sufficient cortisol and aldosterone activity • Ambiguous genitalia
		Nonclassical	• Mildest, not apparent until puberty • Most common: 1/100–1000 Caucasians
11 beta hydroxylase	• 5%–8% of all cases • Autosomal recessive • Chromosome 8	Severe salt wasting	• Cortisol and aldosterone deficient • Ambiguous genitalia • Increased 11-deoxycortisone results in hypertension
		Simple virilizing	• Less severe, compensatory ACTH allows production of cortisol and aldosterone • Ambiguous genitalia • May also have hypertension
		Late onset	• May present later with sexual precocity, hirsutism, and irregular menses
3-beta-hydroxysteroid dehydrogenase	• Two different genes for this enzyme result in two different locations in body sites • All result in mild virilization due to elevated DHEA	Type 1	• Enzyme defects in the placenta and peripheral organs such as skin and breast
		Type 2—salt wasting	• Enzyme defects in more central endocrine organs such as adrenal and ovary • Significant mutation causing severe enzyme defect
		Type 2—nonsalt wasting	• Enzyme defects in more central endocrine organs such as adrenal and ovary • Less significant mutation resulting in mild enzyme defects

Tumor

While a rare cause of HA in the prepubertal population, a diagnosis of malignancy must not be overlooked. Often, these will present with rapid onset and progression, noting a short history of symptoms that also tend to be more severe. Ovarian and adrenal tumors may also result in gonadotropin-independent precocious pubertal development. In the event of suspicion for tumor, imaging studies are recommended of both the ovaries and the adrenal glands. Androgen producing ovarian tumors are usually sex cord stromal in origin and include Sertoli-Leydig cell, Granulosa cell, or hilus cell tumors. Recommended serum hormone markers include testosterone, human chorionic gonadotropin (hCG), DHEA-S, and 17-OHP. Adrenal tumors are classically carcinoma by histology, though may rarely be adenomas.

Other

Other causes of HA in this population are also seen in the postpubertal population and are therefore more appropriately reviewed in the following section. These include idiopathic hirsutism, hyperprolactinemia, Cushing syndrome, and drug ingestion.

Postpubertal

Unlike the prepubertal and postmenopausal populations, the hypothalamic-pituitary axes in both the ovaries and the adrenal glands are fully functional and active during the postpubertal phase. Therein, HA is more commonly seen in this population than in the other extremes of age. Without question, the most common cause of HA in the world is PCOS, though other causes must be evaluated in this cohort as well and warrant discussion in this article.

Polycystic ovary syndrome (PCOS)

The lion's share of HA seen in women that have undergone puberty, but are not yet menopausal, is PCOS ([Azziz et al., 2004](#)). This is the cause of irregular menstrual cycles and HA in 5%–10% of women worldwide, affecting over 100 million women. The complex nature of this multifactorial and diverse disease is impossible to condense into one article; thus, the main focus here will be the HA component of the disease.

PCOS patients manifest HA in approximately 60%–80% of cases, largely from the ovarian overproduction of androgens ([Azziz et al., 2004](#)). As introduced above, this stems in part from an abnormal regulation of the HPO axis whereby the amplitude and frequency of gonadotropin releasing hormone (GnRH) is altered, and thus the delicate balance of LH and FSH expression is also affected, favoring release of LH over FSH and thus increasing the LH:FSH ratio ([Catteau-Jonard and Dewailly, 2013](#)). As seen in the physiologic hyperandrogenism of puberty, any time that LH is significantly increased relative to FSH expression, there is predominance of androgenic precursors in the theca cell of the ovary that cannot be adequately shuttled to estradiol in the granulosa cell. This backup in production of androgenic precursors results in release of these androgens into the bloodstream, making them available for peripheral and systemic effects.

Moreover, PCOS patients commonly manifest a resistance to insulin signaling, augmented in several ways by the concurrent HA. This insulin resistance has several effects. First, it decreases the production of sex hormone binding globulin (SHBG) in the liver, which decreases the binding of androgens to this transport protein, allowing more of the total circulating androgen to be free to exert hormonal effects. Second, insulin can also act in the ovary directly, as a “co-gonadotropin,” to augment the effects of LH in androgen production. Interestingly, insulin action in the ovary via the insulin receptor uniquely favors a certain phosphorylation cascade that leads to downstream inhibition of aromatase, exacerbating the backup of androgen precursors (discussed in more detail below). Finally, it can also bind the insulin like growth factor 1 (IGF-1) receptor, which is present on theca and granulosa cells of the ovary, further modulating steroid hormone production. Therefore, not only does insulin increase free androgens in the serum by decreasing production of its natural “buffer” (SHBG), it also drives production of more androgens directly ([Fritz and Speroff, 2011](#); [Catteau-Jonard and Dewailly, 2013](#)).

Obesity, insulin resistance, and the metabolic syndrome

Many patients with PCOS are obese and insulin resistant, or even have frank metabolic syndrome. Moreover, patients that are obese or insulin resistant are more likely to have PCOS. Thus, the overlap among these conditions is great, in large part due to the effects of insulin on the ovary mentioned above. Insulin acts through several receptors to affect ovarian steroidogenesis, and in fact leads to inhibition of aromatase and stimulation of 17,20-lyase and 17-hydroxylase activity, which results in shuttling the steroid pathway toward production of androgens ([Magoffin, 2006](#); [Yang et al., 2015](#)). In addition to direct steroidogenic actions, insulin also affects the ovary by manipulating the responsiveness to LH and FSH. It does so by preferentially phosphorylating the insulin receptor at serine sites as opposed to tyrosine sites, which alters the function of the receptor to a more proliferative state, increasing FSH and LH receptors on the ovarian granulosa and theca cells, respectively. This augments the responsiveness of the ovary to stimulation from the HPO axis, further increasing steroidogenic signaling while simultaneously inhibiting aromatase, inevitably leading to a buildup of androgens and a deficiency of estradiol ([Fritz and Speroff, 2011](#)). Finally, as mentioned above, there is also a decrease in SHBG production in patients with elevated insulin, and therefore more free androgen in the blood to exert effects.

There is significant overlap with obesity and hyperinsulinemia with PCOS, and sometimes it is clinically difficult to distinguish which condition preceded the other. It is important to note that several syndromes exist where patients have significantly altered insulin sensitivity due to intrinsic receptor defects in the insulin receptor from mutations or autoimmune disease or through some type of abnormal adipose distribution (known as lipodystrophy). The more severe of these syndromes, known as

hyperandrogenic insulin resistant acanthosis nigricans, or HAIR-AN syndrome, bears strong resemblance to PCOS, though again, exhibits extremes of both insulin resistance and HA.

Idiopathic hirsutism

Patients presenting with complaints of clinical HA may not demonstrate elevated serum levels of androgens, nor manifest any other appreciable signs or symptoms other than hirsutism. These patients are classified as having idiopathic hirsutism, which is thought to stem from overactive peripheral enzyme activity in the hair follicles (Azziz et al., 2000; Carmina, 1998). Testosterone may be converted to dihydrotestosterone (DHT), a more potent androgen, by the enzyme 5-alpha reductase, which is present in the hair follicle, and responsible for signaling local hair growth. A small proportion of patients, thought to be approximately 5%–7% of the population presenting with complaints of hirsutism, are thought to have increased activity of this enzyme at the hair follicle (Azziz et al., 2004). Treatment can be difficult as therapies take weeks to months for optimal results, and involves local downregulation of this enzyme, antiandrogens, depilatory agents, or manual removal via laser, shaving, or plucking.

Hyperprolactinemia

Prolactin is yet another hormone released from the anterior pituitary, with one unique caveat. Most hormones are released when a stimulatory signal from the hypothalamus signals their release; however, prolactin is constitutively released unless the release is inhibited by the hypothalamic signal via dopamine. Elevated levels of prolactin can result in increased production of adrenal androgens, specifically DHEA-S, perhaps through direct stimulation on the adrenal gland as prolactin receptors have been identified in the adrenal gland (Fritz and Speroff, 2011). While patients with hyperprolactinemia rarely present with complaints of HA, and indeed, it is rarely the cause of HA, it remains an important consideration in the differential diagnosis.

Cushing syndrome

Cushing syndrome involves elevated levels of cortisol from one of several sources: ingestion of exogenous steroids with cortisol activity, elevated ACTH from a pituitary tumor, elevated cortisol production from an adrenal tumor, or ectopic production of ACTH from another cancer. The latter is a phenomenon known as paraneoplastic syndrome, and classically presents with a particular subtype of lung cancer. Cushing patients not only manifest HA symptoms such as hirsutism, but also several other well-known signs including skin stretching resulting in striae, increasing central obesity, fatigue, muscle weakness, and fat deposition along the back of the neck (termed a “buffalo hump”). Therefore, patients who present with a conglomeration of symptoms such as these described warrant further workup for elevated levels of cortisol. As the overall incidence of this disease is rare (< 1% of HA patients ultimately have this diagnosis) (Fritz and Speroff, 2011), the risk of a false positive test is significant. If initial testing is positive, exogenous sources should be ruled out prior to proceeding to any further testing to localize the source of the overproduction of cortisol (Goodman et al., 2001). The various options of screening for the disease as well as testing strategies to localize the source are beyond the scope of this article.

Tumor

While small benign lesions known as adenomas are not uncommonly found in the pituitary, tumors in the brain that result in overproduction of androgens are quite rare. These would stem from an overgrowth of the pituitary cells known as gonadotrophs that are responsible for the secretion of both LH and FSH. However, adenomas can also grow so large as to affect the hypophyseal portal system, altering the communication between hypothalamic GnRH and the pituitary, resulting in abnormal secretion of some or all of the pituitary end products.

Elevated androgens from tumors in either the ovary or the adrenal gland are rare as well, particularly in this patient population. Suspicion should be high, however, as it is a diagnosis that must not be missed. Again, patients with a malignancy will typically present with more rapidly progressive and more severe symptoms. In these patients, it is prudent to consider imaging the patient's ovaries and adrenal glands to identify a tumor source (Azziz et al., 2004; Carmina et al., 2006; Waggoner et al., 1999).

Iatrogenic

One of the more common causes of HA in any population, and perhaps one of the more commonly overlooked, is iatrogenic HA (Azziz et al., 2004). This usually occurs from the exogenous supplementation of medications that have androgenic side effects, whether by prescription or illicitly. This practice is common in athletes and body builders taking steroids or growth hormone derivatives that result in symptoms consistent with HA. Other prescription drugs that are known for their androgenic actions include DHEA, cortisol, or other steroids such as prednisone and hydrocortisone. Interestingly, Minoxidil, phenytoin, and cyclosporine can result in hypertrichosis, which is a darkening and thickening of hair follicles that can mimic hirsutism, though by a different mechanism of action.

Other

There are also reported cases of extremely rare causes of HA, usually resulting from mutations in enzymes causing deficiencies in the steroid pathway. One such is p450 oxidoreductase deficiency, whereby a mutation on this gene on chromosome 7 affects the ability to provide a specific group of enzymes in the p450 class with the necessary electron donors to be in their active forms. As it happens, this class of enzymes includes some of the hormones in the steroid pathway. Aromatase deficiency is another rare disorder which results in a decreased ability to turn the theca cell precursor androstenedione into estradiol in the granulosa cell, resulting in

a buildup of androgens. Also, defects in glucose metabolism resulting in hyperinsulinemia can cause HA, as previously discussed. Several mutations in the insulin receptor have been reported to cause severe hyperinsulinemia and subsequent HA, for example.

Postmenopausal

The postmenopausal period is one in which the ovary again becomes more quiescent and therefore, is similar to the prepubertal population when HA is overall rare. Interestingly, as the ovary ages, and the number of follicles dwindles, the ratio of theca cells to granulosa cells increases and accordingly, there is a slight increase in androgen production over estrogen. Symptoms from this mild elevation in physiologic androgens are mild, if present at all. The main causes of pathologic HA, similar to the prepubertal cohort, in this patient population include pathologies of overproduction and tumors.

Obesity, insulin resistance, PCOS

As seen in the postpubertal population, patients that experience increased stimulation of the theca cell through various mechanisms will manifest elevated levels of androgens. This is also the case after menopause, whereby patients have higher productivity in these cells producing androstenedione and DHEA, which otherwise would be turned into estradiol if not for the lack of functional granulosa cells in the postmenopausal ovary (Markopoulos et al., 2011). The transiently elevated androgens seen in early menopause discussed above can be further exacerbated by insulin resistance, obesity, or a history of PCOS that can all contribute to further stimulation of this pathway to exacerbate the production of androgens, and result in more impressive HA for these patients. As the ovary continues to atrophy later in life, these symptoms may be ameliorated, though in some patients with enough peripheral stimulation from adiposity and hyperinsulinemia, the androgen production may persist for years.

Ovarian hyperthecosis

Though the exact pathology in this category of HA is not known, ovarian hyperthecosis is characterized by similar symptomatology as PCOS or the metabolic syndrome discussed above. These patients are distinguished, however, by a larger production of androgens driven by an increased gonadotropin secretion from the pituitary (Fritz and Speroff, 2011; Markopoulos et al., 2015). They tend to have isolated high testosterone that is accompanied by high levels of LH and FSH. Ultrasound studies show ovaries larger than expected in menopause, and biopsies of this ovarian tissue have revealed pockets of active cords of cells producing these steroids. With higher levels of androgens, patients will be at higher risk for insulin resistance, obesity, metabolic disease, and, long term, for diabetes and heart disease.

Tumor

Adrenal tumors are rare in this population, though if present are either carcinoma or adenoma. As in the other populations, carcinomas are significantly more likely than adenomas, though still rare overall. Suspicion for adrenal origin is usually reserved for patients that have elevated DHEA-S levels $> 700 \text{ mcg dL}^{-1}$ (Fritz and Speroff, 2011; Waggoner et al., 1999).

Ovarian tumors, while still overall rare, are more common in the postmenopausal population comparatively, with approximately 22,000 cases of ovarian cancer diagnosed in the United States annually. Nonetheless, ovarian malignancies that are capable of producing androgens only comprise a small proportion of this number, making up $< 5\%$ of all ovarian tumors. Again, they tend to be sex cord stromal and bimodal in their presentation, meaning they are more common in the very young or very old populations. As HA is rare at this age and the prognosis of a patient with any malignancy is improved with earlier detection, clinical suspicion must always be high to rule out an ovarian tumor. A serum total testosterone level $> 150 \text{ ng dL}^{-1}$ is suggestive of an androgen producing tumor. Moreover, a tumor is suspected if the onset of HA symptoms such as virilization is over a short period of time, indicating rapid production that would not be consistent with simple theca cell stimulation as in PCOS.

Iatrogenic

Finally, it is worth mentioning iatrogenic HA in this population as well. Many postmenopausal patients will take some form of hormonal replacement therapy for menopausal symptoms at some point, whether over the counter or prescribed. Various treatments available for consumption have levels of androgenic activity and therefore, a thorough review of a patient's medications is prudent prior to other diagnostic modalities.

Conclusion

In conclusion, HA is seen in patients along all ages, and while metabolic disturbances such as PCOS or glucose intolerance are the most common pathologies involved, it is important to bear in mind all the potential causes. All patients presenting with symptoms of HA should be thoroughly evaluated and concern for malignancy should be ruled out, particularly in cases where the onset of symptoms is rapid or severe. It is also important to consider the relationship between HA and insulin resistance, noting that long-standing HA may alter physiology, increasing or exacerbating risk for chronic medical conditions such as diabetes and hypertension; thus, control over HA and appropriate screening and counseling are strongly recommended.

Thyroid Function and Reproduction

Dina M Abdelsamad, Ain Shams University, Cairo, Egypt

Introduction

Our endocrine system is a highly sophisticated hierarchical system that dictates efficiency as well as dynamic control of different processes in our body such as metabolism, growth, and sexual and emotional development. The thyroid gland is unique among the endocrine organs as it maintains a large store of hormone. The thyroid gland is a brown-red highly vascular gland located anteriorly in the lower neck extending from the fifth cervical vertebra down to the first thoracic vertebra. It weighs approximately 25 g but can be slightly heavier in females and can change in size during menstruation and pregnancy. The estimation of the size of the thyroid gland can be easily achieved noninvasively by clinical examination (Strandberg, 2016).

The thyroid gland is wrapped in an outer false and an inner true capsule, which separates the gland dividing its lobes into lobules. Cystic follicles are the main structural units of the gland and are lined by single epithelial layer surrounding a colloid filled cavity. The principal (follicular) cells produce thyroglobulin (Tg), a dimeric protein used by the gland as a precursor to thyroid hormones. In addition to the principal follicular cells, parafollicular cells (clear cells) secrete calcitonin hormone which is involved in the calcium homeostasis process. An extensively dense network of fenestrated capillaries, lymphatic vessels, and sympathetic nerves oversees the follicles whose size changes according to their activity and hence the abundance of colloid material (Strandberg, 2016).

Synthesis and Regulation of the Thyroid Hormone

Thyroid hormones are produced when the tyrosine residues of thyroglobulin are combined with iodine and the protein is cleaved by action of the enzyme thyroid peroxidase (TPO). Thyroxine (T₄) is the main hormone secreted by the thyroid gland with a longer half-life, though biologically less active, than triiodothyronine (T₃) which is primarily produced outside of the thyroid gland. The thyroid gland secretes 80 µg thyroid hormone daily and is highly dependent on the availability of iodine (Hedden et al., 2015).

More than 99.5% of the circulating thyroid hormones is carried on plasma proteins, mainly thyroxine binding globulin (TBG), transthyretin (TTR), and albumin. The hypothalamic pituitary thyroid axis regulates thyroid hormone homeostasis in the body. Thyroid-stimulating hormone (TSH) secreted from the anterior lobe of the pituitary gland regulates secretion of thyroid hormone. Thyroid-releasing hormone (TRH), produced from the periventricular nucleus of the hypothalamus, regulates secretion of the TSH. This axis is regulated by T₃ and T₄ action on anterior pituitary and hypothalamus using feedback mechanism (Yamada and Mori, 2008).

After conception, TBG and total T₄ concentrations levels are detected in plasma and increase starting from week 7 of gestation and peak by week 16. These concentrations then remain high until delivery. In the first trimester, maternal human chorionic gonadotropin (hCG) directly stimulates the TSH receptor, increasing thyroid hormone production and serum TSH concentration falls. Therefore, during pregnancy, women have lower serum TSH concentrations than before pregnancy, and a TSH below the nonpregnant lower limit of 0.4 mU L⁻¹ is observed in as many as 15% of healthy women during the first trimester of pregnancy. The fraction of women with a suppressed TSH falls to about 10% in the second trimester, and 5% in the third trimester (Poppe et al., 2007; Alexander et al., 2017).

Epidemiology and Classification of Thyroid Disorders

Thyroid disorder classification is based on the levels of thyroid hormone in blood. Euthyroidism, hyperthyroidism, and hypothyroidism reflect the clinical states of normal, excessive, or defective levels of thyroid hormones. In areas of the world with dietary iodine deficiency, an enlargement of the thyroid termed goiter is common. On the contrary, in iodine-replete areas autoimmune etiology is the cause for thyroid disorders, either hypothyroidism including Hashimoto's thyroiditis to hyperthyroidism including thyrotoxicosis caused by Graves' disease (Vanderpump, 2011).

Primary hypothyroidism has a lifetime prevalence as high as 9% for women and 2% for men. The causes can be congenital or iatrogenic but more frequently are autoimmune in origin. The most common cause of hypothyroidism associated with antithyroid autoantibodies is six times more common in females than males. Hashimoto's thyroiditis is more common in middle age women and associated with very high titers of thyroid peroxidase (TPO) antibodies. Postpartum thyroiditis is usually self-limiting following pregnancy but can be permanent if antibodies are detected. Secondary hypothyroidism is due to hypopituitarism from pituitary adenoma, pituitary ablative therapy, or pituitary destruction.

Subclinical hypothyroidism also called mild thyroid failure, is diagnosed when peripheral thyroid hormone levels are within normal reference laboratory range but serum thyroid-stimulating hormone (TSH) levels are mildly elevated (Fatourechi, 2009). The worldwide prevalence of subclinical hypothyroidism ranges from 1% to 10%.

On the other hand, hyperthyroidism affects 2%–5% of females at some time during their life and occurs five times more commonly in women than men. Primary hyperthyroidism is associated with thyrotoxicosis when tissues are exposed to high levels of thyroid hormones. The most common causes of hyperthyroidism are Grave's disease, toxic multinodular goiter, and solitary toxic nodules; the less common causes are the infectious causes, gestational thyrotoxicosis or due to drugs (Kumar and Clark, 2017).

Antithyroid antibodies can be detected in the serum of individuals who are hypothyroid, hyper thyroid, or euthyroid. The presence of autoimmune thyroid antibodies without thyroid dysfunction can be considered a precursor of an upcoming thyroid dysfunction (Monaco, 2003). These antibodies can be destructive such as those directed against thyroglobulin (Tg Ab) or thyroid peroxidase antibodies (TPO Ab). Other antibodies such as those directed against the TSH receptor (TSHR Ab) mostly stimulate, but occasionally block, TSH receptor. TSHR Ab are highly specific for Grave's disease (Kumar and Clark, 2017). TPO Ab are present in 20% of the normal population but only 10%–20% will develop overt hypothyroidism. The IgG TPO AB are able to cross the placenta but do not appear to cause any fetal thyroid dysfunction (Alexander et al., 2017).

Screening for Thyroid Disorders

Serum thyrotropin (TSH) shows a log-linear relationship to free thyroxine. The assay of TSH is commonly accepted as the most sensitive test to detect minor degrees of primary thyroid hormone deficiency. TSH assays are standardized and offer a cost effective method for screening for thyroid disorders (Blumenthal and Eastman, 2017). TSH level elevation in the presence of normal free thyroxine serum levels is defined as subclinical hypothyroidism. Subclinical hypothyroidism is a proven risk factor for the development of overt thyroid dysfunction and for other clinical, mainly cardiovascular, cognitive, and psychiatric disorders. Historically, the range of normal for TSH has been set at approximately 0.4–4.5 mIU L⁻¹. Large population studies have suggested a lower TSH cut-off with an upper limit of 2.5 mIU L⁻¹ in women of reproductive age (Brabant et al., 2006). A comparison of the guidelines from the American Society for Reproductive Medicine, the American College of Obstetricians and Gynecologists, The Endocrine Society, and the Royal College of Obstetricians and Gynaecologists concerning testing and treatment of thyroid disease are listed in Table 1.

It is noteworthy that pregnancy may confound the interpretation of the normal TSH range. In 2007, The Endocrine Society and the American Thyroid Association recommended that the upper limit of the TSH reference range be lowered to <2.5 mIU L⁻¹ in the first trimester and <3 mIU L⁻¹ in the second and third trimesters of pregnancy (Stagnaro-Green et al., 2011). In accordance with these findings, in 2012 The Endocrine Society guidelines recommended treating pregnant women or women planning a pregnancy when serum TSH exceeds 2.5 mIU L⁻¹ in the first trimester and 3 mIU L⁻¹ in the second and third trimesters (DeGroot et al., 2012).

The Effect of Thyroid Hormone on Female Reproductive Physiology

Disorders of thyroid function have a negative impact on female reproduction. Both hypothyroidism and hyperthyroidism have been associated with menstrual disturbances and ovulatory dysfunction. These disturbances sometimes antedate the clinical diagnosis of thyroid dysfunction (DeGroot et al., 2012). Since human oocytes have receptors for thyroid hormone (López Navarro et al., 2016), thyroid hormone disturbances can affect oocyte maturation and ovulation through the change in prolactin levels, alteration of GnRH pulsatile secretion leading to a delayed response of LH and inadequate corpus luteum function (Poppe et al., 2007; Jefferys et al., 2015).

Both increased and decreased levels of thyroid hormone may cause menstrual disturbances, mainly hypomenorrhea and polymenorrhea in hyperthyroidism and oligomenorrhea in hypothyroidism. Hyperthyroidism causes increased circulating sex hormone binding globulin (SHBG) in serum resulting in estrogen levels that may be doubled or tripled. In hyperthyroid women the mean LH levels in both the follicular and luteal phases of the menstrual cycle are significantly higher compared to normal women. In hypothyroid women these physiological changes are skewed to the opposite end of the curve though GnRH levels remain within normal (Krassas et al., 2010).

Table 1 Endocrine Societies guidelines for TSH and antithyroid antibody testing

Guideline recommendation	ASRM	ACOG	Endocrine Society	Royal College
Routine TSH testing	No	No	No	No
Routine TPO/TG antibodies	No	No	No	Not discussed
Treatment if TSH > 2.5	No, if TSH > 4.0	No	Yes	No
If TSH > 2.5 and TPO Ab/TG Ab positive	Yes, if clinically indicated	No	Yes	Not discussed

Autoimmune thyroid disease (AITD) is the most common cause of hypothyroidism in women in the reproductive age group 20–40 years. Overt hypothyroidism is associated with a broad spectrum of reproductive disorders, ranging from abnormal sexual development, menstrual irregularities to infertility (Poppe et al., 2007).

Thyroid Disorders and Infertility

Infertility is the failure to conceive after 1 year of unprotected intercourse and is found to affect about 10%–15% of couples in reproductive age (Puscheck and Scott, 2016). In women presenting with fertility issues 2.3% are hyperthyroid, 2%–4% have overt hypothyroidism (Jefferys et al., 2015). In women with ovulatory disorders and irregular menstruation 9%–11% were found to have subclinical hypothyroidism (Lincoln et al., 1999; Poppe, et al., 2007). Among women presenting with infertility, TSH levels were highest among women with ovulatory dysfunction and irregular menstruation (Lincoln et al., 1999).

The prevalence of autoimmune thyroid disease (AITD) is 5–10 times more in women than in men and also higher in women suffering from infertility when compared to an age-matched parous group of women (Ke, 2014). AITD is generally defined as the presence of reactivity to self-thyroid antigens, which are expressed as distinctive inflammatory or antireceptor autoimmune diseases (Iddah and Macharia, 2013). Antithyroid antibodies are also detectable in the ovarian follicles of women with thyroid autoimmunity. The presence of antithyroid antibodies in women with PCOS has been reported to decrease the response of ovaries to clomiphene citrates (Alexander et al., 2017).

The adverse effect of hypothyroidism on fertility can be through the alteration of the estrogen metabolism peripherally, increasing the level of prolactin, which in turn causes negative feedback inhibition on the GnRH level, and the decrease in the levels of SHBG (Hoffman et al., 2016). Most of evidence suggests that IVF outcomes do not differ between women with serum TSH $< 2.5 \text{ mU L}^{-1}$ and those with very mild TSH elevations, defined as a TSH between 2.5 and 4.0 mU L^{-1} . A proposed clinical algorithm for the evaluation of reproductive aged women based on TSH results is presented in Fig. 1.

Despite the physiological evidence that thyroid gland dysfunction influences fertility, AITD alone do not affect embryo implantation (Poppe et al., 2003). The presence of antithyroid antibodies did not affect implantation rates in over 700 euthyroid patients who went through IVF (Kutteh et al., 1999). A recent study found no link between preconception subclinical hypothyroidism and time to pregnancy (Plowden et al., 2016). The presence of AITD did not affect implantation rates in women with a normal thyroid function who went through IUI. Unfortunately, follow-up of patients showed that the patients with AITD have significantly elevated risk of pregnancy loss in the first trimester even if they became euthyroid before conception.

Thyroid Disorders and Pregnancy Loss

Early pregnancy loss is a frustrating and heart-wrenching experience for both the patient and the physician. Almost 25% of women will experience at least one miscarriage, while 2%–4% of couples will suffer recurrent pregnancy loss (Kutteh, 2015). In addition to infertility, miscarriage, preeclampsia, and abruption placenta have been associated with thyroid dysfunction. Fetal complications

Fig. 1 Proposed clinical algorithm based on TSH results for assessment of reproductive aged women. *TSH*, thyroid stimulating hormone; *TPO Ab*, thyroid peroxidase antibody; *TG Ab*, thyroglobulin antibody.

including preterm birth, low birth weight, impaired neurocognitive development, and fetal death have also been correlated with disorders of thyroid function. A Dutch study of nearly 2500 pregnant women demonstrated that as TSH values rise there is an increased risk for fetal loss (Benhadi et al., 2009).

Among pregnant women, autoimmune thyroid disease has a prevalence of 5%–20% depending on the population studied (Glinioer, 2009). Women demonstrating antithyroid antibodies (ATA) during pregnancy have shown that despite the expected decrease in antibody titers during gestation, thyroid function gradually deteriorated toward hypothyroidism in a significant fraction of such women (Glinioer et al., 1994). The most commonly targeted thyroid antigens are thyroid peroxidase (TPO) and thyroglobulin (Tg), both integral to the production of T4 and T3. The reported prevalence of anti-TPO and anti-Tg antibodies in asymptomatic women is 14.6% and 13.8% respectively (Hollowell et al., 2002).

Stagnaro-Green (1990) first reported an association of ATA with pregnancy loss observing a doubling of the spontaneous miscarriage rate (17.0 vs. 8.4%; $P = 0.001$) in women with a TSH between 2.5 and 5.0 mIU L⁻¹ who were ATA-positive compared with an ATA-negative cohort. A pooled analysis of 21 studies (13 cohort and 8 case control) demonstrated an odds ratio of 2.55 [CI 1.42–4.57; $P = 0.002$] for recurrent losses in women with ATA (Chen and Hu, 2011). Similarly, a recent meta analysis showed a positive association of ATA with spontaneous pregnancy loss in both cohort [OR 3.9 CI: 2.48–6.12; $P < 0.001$] and case-control [OR 1.8; 95% CI 1.25–2.6; $P = 0.002$] studies (Thangaratinam et al., 2012). Based on these studies, a clinical algorithm for the testing of reproductive aged women based on the results of TSH testing along with ATA testing is proposed in Fig. 1.

The precise pathogenic link between ATA and pregnancy loss is unknown and the association does not imply a causal relationship. Autoimmune thyroid disease may impair thyroid reserve to such an extent that the gland is unable to respond to the challenge of pregnancy. ATA may be associated with inappropriate low levels of thyroid hormones for the given gestational period, despite apparent biological euthyroidism. Alternatively, autoimmune thyroid disease could act by delaying the occurrence of conception because of its known association with infertility. Similarly, women with autoimmune thyroid disease are generally older than healthy controls and increased age is an independent risk factor for miscarriage. Finally, ATA may merely be a marker for a generalized immune imbalance that may independently promote pregnancy loss (Glinioer, 2009; Kaprara and Krassas, 2008).

Regardless of the causal relationship, there is evidence that thyroid hormone replacement with levothyroxine in pregnant women with hypothyroidism (TSH > 2.5 mIU L⁻¹), will improve pregnancy outcome (Abalovich et al., 2002; Bussen et al., 2000; Negro et al., 2006). Furthermore, a Cochrane study suggested a significant reduction in preterm birth and a trend toward reduced miscarriage when levothyroxine was used in euthyroid pregnant women with ATA (Reid et al., 2013). Given that thyroid autoimmunity may be present for many years before the onset of hypothyroidism, it seems reasonable to test RPL patients for ATA (both anti-TPO and anti-Tg), preferably immediately before conception. For those with positive antibodies and a TSH > 2.5 mIU L⁻¹, levothyroxine therapy tailored to the TSH level is indicated (Negro et al., 2006). Close monitoring, particularly in the first trimester, is important because of rising thyroid demands with dosage often requiring titration upward during pregnancy (Mandel et al., 1991). There are no clear recommendations in ATA-positive pregnancies with a normal TSH (TSH < 2.5 mIU L⁻¹) but common sense dictates that at the very least, close follow-up during pregnancy is warranted.

Glossary

Amenorrhea Absence of periods.

Anti-Mullerian hormone (AMH) Ovarian hormone produced by small antral follicles.

Dyspareunia Pain on intercourse.

Iatrogenic Caused by medical or surgical treatment.

Idiopathic Of unknown cause.

Karyotype Chromosome complement.

Oligomenorrhea Infrequent periods.

Osteoporosis Condition of weakened bone at risk of fracture.

Ovarian reserve Term used to indicate the reproductive potential of the ovary; often used as well to indicate the relative number of eggs remaining in the ovary.

Introduction

Premature ovarian insufficiency (POI) affects 1% of women. It is defined as loss of ovarian activity under the age of 40 years and is characterized by infrequent or absent periods (oligomenorrhea or amenorrhea respectively) and elevated follicle stimulating hormone (FSH). Although it is irreversible, those affected may have episodes of spontaneous ovarian activity, when ovulatory cycles may resume and may even be regular for a limited time. It is for this reason that classifying it as a *premature menopause* or *ovarian failure* is inaccurate. In addition, and importantly, affected women find both these terms unacceptable. Primary ovarian insufficiency is an alternative and accurate name for the condition, indicating that it arises within the ovary, but should not be confused with primary or secondary amenorrhea, as the condition can present with either ([Table 1](#)).

POI is a cause of infertility but natural pregnancies do occur in a small number of women with POI following spontaneous ovulation. Apart from infertility, the consequences of POI are believed to be secondary to low estrogen. Vasomotor symptoms (i.e., hot flashes and night sweats) and osteoporosis can be treated effectively with hormone replacement. However, affected women have a reduced life expectancy, mainly due to cardiovascular disease but also osteoporosis, and data supporting the role of hormone replacement in reversing these complications are, as yet, lacking.

POI can be spontaneous or a consequence of medical or surgical treatments for benign or malignant disease (iatrogenic) in approximately equal numbers ([MacLaran and Panay, 2011](#)). An increasing number of women are living with POI after surviving cancer, although fertility-sparing treatments are now being used when feasible. The major cause of spontaneous POI is unknown, or idiopathic. Genetic causes account for the minority of cases and in an even smaller minority the cause is autoimmune.

Clinical Features

POI presents in females under the age of 40 years with amenorrhea of at least 4–6 months duration, in the presence of elevated FSH levels on two or more occasions a minimum of 4 weeks apart. Amenorrhea may be primary (when there has never been a menstrual period) or secondary (cessation any time after menarche, the first menstrual period). POI presenting with primary amenorrhea may be associated with delayed or arrested puberty and is more likely to be associated with an underlying chromosomal or genetic condition.

The diagnostic cut off level for FSH has not been formally validated, although many biochemistry laboratories will quote > 30 mIU/mL as being “menopausal.” FSH levels tend to be higher in idiopathic POI compared to autoimmune causes ([La Marca](#)

Table 1 Proportion of women experiencing menopause by age

Average age	10% by	1% by	0.1% by	0.01% by
51 years	45 years	40 years	30 years	20 years

The average age of menopause in the United Kingdom is 51 years. The table shows the proportion of women who have undergone menopause by a given age ([POI Guideline Development Group, 2015](#)).

et al., 2009). A review of the literature found levels of 20, 30, and 50 mIU/mL have been used and the ESHRE Guideline on the management of POI proposed a cut off level of 25 mIU/mL to ensure inclusion of those with autoimmune POI (POI Guideline Development Group, 2015).

It is important not to confuse POI with low ovarian reserve, the difference being that women with low ovarian reserve are still having menstrual cycles even though FSH levels may be above the 25 mIU/mL cut off. These conditions are on the same spectrum, however, and some women with low ovarian reserve will progress to POI.

One of the features of POI is that ovarian function can fluctuate, especially within the early years of the condition presenting. In some women, this will result in the resumption of menstrual cycles after a prolonged episode of amenorrhea. Periods may be sporadic but in some can become regular and ovulatory for variable lengths of time.

Women with POI may experience hot flashes and night sweats, the classic symptoms of low estrogen. However, young women and adolescent girls with POI often do not, suggesting that these symptoms represent an estrogen withdrawal effect rather than absolute levels of low estrogen. Genito-urinary symptoms are common throughout the age range, especially dyspareunia in sexually active women. These symptoms can be distressing, although are often not disclosed by affected women unless prompted. Sexuality is often affected and the causes are likely to be multifactorial. The associated infertility of POI may affect how a woman (or her partner) view sexual relations. The underlying diagnosis may have a psychological impact, for example, fear of passing on a genetic cause should pregnancy occur. There may also be physical consequences in iatrogenic POI such as a shortened or stenosed vagina after surgery or radiotherapy.

Osteoporosis is a consequence of POI irrespective of the cause, although there are no data to indicate whether the risk of fracture is increased. Cardiovascular morbidity and mortality are also increased and this is the main reason for the reduced life expectancy seen in POI.

Women with surgical POI may experience a decline in memory in the short-term. The evidence is conflicting as to whether there is a longer-term risk of dementia and Parkinson's disease in this group (Vearncombe and Pachana, 2009). With the exception of women with Turner syndrome, there are no published data on cognitive function in women with spontaneous POI who are not taking estrogen replacement.

Etiology

POI results when the resting pool of primordial follicles is effectively depleted. In most cases this is due to a reduction in primordial follicle number from an unknown cause, but POI can result from, for example, FSH receptor mutations, meaning that a normal number of primordial follicles are present, but follicle development is arrested (Table 2).

Spontaneous POI

It is not known whether women with idiopathic POI are born with a reduced number of primordial follicles or whether they undergo an increased rate of follicle loss (atresia), resulting in early follicle depletion. However, the commonest genetic causes are X chromosome related.

Chromosomal

Two functioning X chromosomes are required to form a primordial follicle in the fetal ovary. Females with Turner syndrome (TS) are 45XO, lacking one X chromosome. They invariably develop POI early and affected girls often require puberty induction, although sometimes puberty will commence but then arrest. Females who are TS mosaics have cells that are 46XX as well as cells that are 45XO. Girls who are TS mosaics may have normal puberty and regular cycles even into adulthood. However, most will present with POI in adolescence or soon after. Women with Turner syndrome, including mosaics, carry particular risks during pregnancy and this is discussed further in the section on Fertility and Pregnancy.

Genetic

It is estimated that 7% of spontaneous POI is due to carriage of a premutation of the fragile X mental retardation 1 gene, FMR-1, which lies on the X chromosome (Schwartz et al., 1994). Fragile X syndrome is a cause of autism, presenting with developmental problems and cognitive impairment. Boys are more severely affected than girls. The mutation is an increase in the number of trinucleotide (CGG) repeats, a high number of repeats (>200) being associated with the syndrome. A lower number of repeats

Table 2 Causes of premature ovarian insufficiency

<i>Spontaneous POI</i>	<i>Iatrogenic POI</i>
Idiopathic	Surgical
Genetic	Chemotherapy
Chromosomal	Radiotherapy
Autoimmune	

(55–200) is known as a premutation, but is unstable and can increase to the full mutation due to instability during meiosis in females (but not males). Female carriers of the premutation do not have any increased risk of cognitive impairment but have an increased risk of developing POI of 13%–26%, although carriers of the full mutation have no increased risk of POI (Bennett et al., 2010).

Maternal carriage of the premutation may have implications for the offspring, should spontaneous pregnancy occur and the full mutation be present. There may also be implications for family members who carry the premutation and so be at risk of POI or of having an affected child. The Genetics Committee of the Society of Obstetricians and Gynecologists of Canada (2008) therefore recommended routine testing for women with spontaneous POI, pretest counseling being a prerequisite.

A number of autosomal gene mutations have been implicated in the etiology of POI. Some of these are associated with recognized clinical syndromes, for example, type 1 blepharophimosis epicanthus ptosis syndrome (BEPS) and galactosemia. However, most mutations have been identified as a result of investigation of affected families (where the mutation(s) may be limited to that particular pedigree), screening of candidate genes (i.e., looking for mutations of genes known to be involved in follicle development or ovarian function), and, more recently, genome-wide association study (Perry et al., 2013). There is also interest in copy number variations (CNVs) which are large areas of DNA that vary in number between individuals and have regulatory roles in gene expression. This raises the possibility that some of the long-term consequences of spontaneous POI could be due to altered expression of genes rather than the consequences of low estrogen.

Autoimmune

There appears to be an association between autoimmune disorders and POI and autoimmune markers are identified in approximately 25% of women with spontaneous POI (Conway et al., 1996). It is disputed whether the relationship is causative (La Marca et al., 2010) and the clinical usefulness/cost effectiveness of screening for coexisting autoimmune disorders is contentious in the absence of suggestive signs or symptoms.

Histological evidence of ovarian inflammation (oophoritis) has been described in POI, although exclusively in the presence of steroid cell autoantibodies detectable in peripheral blood (Hoek et al., 1997). Selective destruction of theca cells is seen, which is the ovarian component binding steroid cell autoantibodies in ovarian biopsies (La Marca et al., 2010). Estrogen levels are low due to loss of theca cells, and FSH and inhibin B are raised, but anti-Müllerian Hormone (AMH) may be relatively normal until such time as follicle numbers decline significantly, usually becoming undetectable within 5 years (Falorni et al., 2012).

Adrenocortical antibodies (ACA) or 21-hydroxylase autoantibodies (21OH-Abs) are the most sensitive autoantibodies to measure as SCA can be identified in over 90% of cryostatic sections of ovaries taken from women who were positive for either of these. The ESHRE Guideline on Management of POI recommends considering screening for either of these autoantibodies when the cause of POI is unknown or if an autoimmune disorder is suspected in order to detect latent Addison's disease. However, only one group has reported the prevalence of these antibodies in POI (4%–5%; Falorni et al., 2012) and a small case series identified progression to impaired adrenal function within 5 years in three out of four women with POI who were positive for ACA (Betterle et al., 1997). Women with autoimmune Addison's disease, invariably positive for ACA/21OH-Abs, and a component of the autoimmune polyendocrine syndromes—APS-1 and APS-2, which also feature POI—should be counseled about and screened for POI.

It is possible that autoantibodies may exist to other components of ovarian follicles, destruction or blockade of which could cause POI. Case reports have been published of autoantibodies against the LH receptor, FSH receptor and zona pellucida (Kelkar et al., 2005), but the clinical application of testing for these is not supported outside of a research program.

Thyroid autoimmunity and dysfunction may be more prevalent in women with POI compared to the normal population (Welt, 2008), where thyroid peroxidase antibodies (TPO-Ab) are found in 12%–15%. Untreated hypothyroidism affects quality of life and, when present in pregnancy, fetal neurocognitive development. The impact of subclinical hypothyroidism on pregnancy outcome is more contentious but is increasingly treated in the context of assisted reproduction. ESHRE consequently recommended testing for thyroid antibodies in women with spontaneous POI (POI Guideline Development Group, 2015).

There is little evidence to support routine testing for other autoimmune conditions in women with karyotypically normal spontaneous POI. However, the possibility of coexisting autoimmune conditions should be considered at routine clinical review. The exception to this approach may be for women with Turner syndrome, who have an increased risk of celiac and inflammatory bowel disease compared to women with karyotypically normal spontaneous POI and to the normal population (Bakalov et al., 2012).

Iatrogenic POI

Bilateral oophorectomy is an obvious cause of POI but ovarian surgery, especially if bilateral or repeated and particularly if for bilateral ovarian endometriosis can terminally compromise ovarian function (Coccia et al., 2011). However, any extensive pelvic surgery can precipitate POI, thought to be due to disturbances of collateral blood supplies.

Age-standardized cancer rates for men and women are increasing, whereas mortality rates are falling in most countries according to WHO figures. This means that more individuals are surviving cancer but living with the consequences of treatment(s), one of which, for women, can be POI. Chemotherapy and pelvic radiotherapy are both gonadotoxic, although dose and age at delivery affect the impact of either. Different chemotherapeutic agents and combinations of agents have differing effects on the ovary. Alkylating agents, for example, busulphan, chlorambucil and cyclophosphamide, carry the highest risk of POI. Others such as vincristine and

5-fluorouracil have a low risk. Concerns about future fertility are significant for women of reproductive age with cancer ([Tschudin and Bitzer, 2009](#)) and the use of fertility preserving techniques may be appropriate for some.

Bone marrow and stem cell transplantation, which require conditioning chemotherapy (the former requires conditioning total body irradiation as well), are increasingly being used for benign conditions such as sickle cell anemia, thalassemia major and, recently, multiple sclerosis. POI may result from treatment and the risks may be increased depending on the condition being treated. For example, females with sickle cell anemia may have preexisting compromised ovarian reserve due to the effects of sickle cell on ovarian blood supply.

Treatments

The only treatment for POI is to replace the estrogen that is no longer being produced by the ovaries. It is not possible to re-populate the ovary with follicles, as these are only produced during fetal life. The primary aim of estrogen replacement is to treat or prevent the consequences of low estrogen. The only proven benefits are for symptoms of low estrogen (hot flashes, night sweats, genitourinary symptoms). Estrogen replacement can also treat or prevent osteoporosis. There is no evidence currently that it prevents bone fractures due to osteoporosis in women with POI (although this is the case in normally menopausal women), but it is biologically plausible that it does. Estrogen replacement may reduce cardiovascular risk factors in women with POI. However, it is not known if it reduces the cardiovascular morbidity or mortality or has any effect on life expectancy. The decline in memory reported in women following oophorectomy can be treated or prevented by estrogen replacement. Women with spontaneous POI taking estrogen replacement have no difference in cognitive function compared to normal controls, although only one paper has addressed this issue ([Ross et al., 2004](#)): however, it is not known if untreated women show any impairment.

As in postmenopausal women, women with POI and an intact uterus should take a progestogen to protect the endometrium from the effect of unopposed estrogen, which could lead to endometrial cancer. Those without a uterus only need to take estrogen and do not require a progestogen. Estrogen and progesterone can be delivered orally or transdermally, and a progestogen can be delivered locally as an intrauterine system as an alternative. Regimens for combined hormone replacement therapy (HRT) can be cyclical (where a progestogen is taken intermittently, usually resulting in a withdrawal bleed), or continuous, to avoid a vaginal bleed. Most young women with POI will require a cyclical combined regimen (unless fitted with a progestogen-releasing intrauterine system), as troublesome vaginal spotting often occurs with a continuous combined replacement due to endometrial instability ([Webber et al., 2017](#)).

Women with POI should be encouraged to adopt healthy lifestyle choices: for example, maintaining a healthy weight and not smoking. This advice applies to the general population, but it may be particularly important for women with POI, given their predisposition to cardiovascular disease and the possibility of cognitive impairment.

Fertility and Pregnancy

Natural pregnancy may occur in up to 5% of women with POI (excluding those after bilateral oophorectomy; [Bidet et al., 2011](#)). There are no proven fertility treatments for women with POI, apart from egg donation, which has an excellent live birth rate, just under 30% per embryo transfer (UK national average in 2015, HFEA). Maintaining the health of the uterus with HRT may be beneficial for future egg donation, and may have a positive effect on the chance of implantation should natural conception occur. It is important that women with POI understand that HRT does not prevent resumption of ovarian activity and, if they are sexually active but want to avoid pregnancy, then contraception should be used.

Spontaneous pregnancies in women with idiopathic POI or after most forms of chemotherapy have no increased risks compared to the normal population. Egg donation pregnancies in those with surgical POI or spontaneous, karyotypically normal POI also appear to have no additional risks in pregnancy compared to any woman who is the recipient of egg donation. The exception is women with autoimmune POI if they have undiagnosed latent Addison's disease, which could be uncovered by pregnancy.

Previous exposure to most chemotherapeutic agents is associated with little risk in a later pregnancy ([Scottish Intercollegiate Guidelines Network \(2013\)](#)). However, anthracyclines and high dose cyclophosphamide can be associated with cardiomyopathy, as can radiotherapy to the heart (e.g., scatter from irradiation to the breast in the treatment of breast cancer, or to treat mediastinal lymphoma). This might be at a subclinical level but could become clinically significant with the physiological stress of pregnancy. Pelvic irradiation often leaves the uterus unresponsive to hormone preparation and implantation will often not occur. If pregnancy does result, there are increased risks of miscarriage (early and late), and disorders of poor placentation (e.g., preeclampsia, stillbirth, and low birth weight) as well as postpartum hemorrhage.

Both natural and egg donation pregnancies are very high risk in women with Turner syndrome (including in those who are a mosaic) due to congenital cardiac anomalies and the risk of aortic dissection, which can be fatal. The estimated risk of a major obstetric complication is 10% and the maternal mortality rate is 3.5% ([Hadnott et al., 2011](#)). Women with TS who desire pregnancy should be referred to a cardiologist specializing in congenital cardiac disease for pre-pregnancy assessment and ongoing care during pregnancy.

Prevention

The risk of iatrogenic POI can be reduced by implementing fertility-sparing treatments when possible. This includes surgical techniques and ovary-sparing surgery, the use of chemotherapeutic agents that are less gonadotoxic and ovarian transposition to remove the ovaries from radiation fields. There are no known options for reducing the risk of spontaneous POI, although maintaining

a healthy lifestyle may be of benefit. Preimplantation genetic screening can be employed for those carrying a mutation known to cause POI to avoid its transmission to the offspring.

Introduction

The World Health Organization (WHO) defines obesity as the presence of excess body weight, classified into categories according to body mass index (BMI) ([World Health Organization, 2000](#)). The prevalence of overweight and obesity ($\text{BMI} > 25 \text{ kg/m}^2$ and $\text{BMI} > 30 \text{ kg/m}^2$, respectively) has increased globally in recent decades, with many developed nations reporting up to 60% of individuals classified as overweight or obese in the 20–39 year age bracket ([Ogden et al., 2006](#)). Although the health effects of excess adipocyte deposition are potentially better correlated with measures of central adiposity such as waist-hip ratio (WHR), public awareness of the concept of BMI and the ongoing use of pre-pregnancy or pregnancy booking BMI in the majority of studies in this area has led to the use of BMI as a standard measure of excess weight ([Mitchell and Shaw, 2015](#)). Similarly, the Institute of Medicine guidelines on gestational weight gain ([Institute of Medicine National Research Council Committee to Reexamine IOM Pregnancy Weight Guidelines, 2009](#)) have been extensively validated and remain a useful resource for clinicians providing advice regarding appropriate weight gain based on BMI category at the commencement of pregnancy.

Regardless of the measure used, it is vital that the clinical sequelae of obesity are detected in patients with obesity in the reproductive age group. Although cardiometabolic health concerns have traditionally been the focus of health prevention activities in this area, the spectrum of adverse effects on reproductive outcomes in both men and women is increasingly recognized as an area of major concern. This chapter focuses on the impact of obesity across the reproductive lifespan, from puberty to fertility, pregnancy, and menopause ([Fig. 1](#)). The trans-generational health effects of the current obesity crisis must also be considered, in recognition of the fact that preconception and pregnancy-related obesity may increase the risk of childhood and adult obesity in future generations ([Mullins et al., 2016](#)).

Fig. 1 Consequences of obesity across the reproductive lifespan and trans-generational effects via in utero exposure to maternal obesity.

Obesity and Puberty

The 'critical weight' hypothesis states that an upper threshold of body weight must be attained before menses can commence (Frisch and Revelle, 1970). The presumed teleological basis is that sexual maturation should only occur when an individual is of an adequate weight and nutritional status to bear offspring (Wagner et al., 2012). The corollary is that excess weight may cause advancement of puberty. The majority of data indicate that obesity is associated with earlier menarche (Al-Awadhi et al., 2013; Freedman et al., 2002; Kaplowitz et al., 2001; Lee et al., 2007; Zhai et al., 2015), although some data show that the age of menarche may be unaffected (Demerath et al., 2004) or even delayed by obesity (Kleber et al., 2011). Obesity prevalence is typically higher among children with premature pubarche (de Ferran et al., 2011; l'Allemand et al., 2002), but one study showed delayed pubarche in obese children (Kleber et al., 2011). The relationship between obesity and puberty is more robust for breast development, with multiple studies showing that thelarche occurs earlier in obese compared to normal-weight girls (Heger et al., 2008; Kaplowitz et al., 2001; Lee et al., 2007; Zhai et al., 2015). Body fat percentage and BMI are greater in girls in whom the first sign of puberty is thelarche compared to girls who present with pubarche (Biro et al., 2003). Genetic factors may account for discrepancies between pubertal processes and between studies (Wagner et al., 2012). The rate rather than the final amount of weight gain may influence pubertal onset as rapid weight gain in infancy is associated with early adrenarche (Dunger et al., 2006) and early menarche (Ong et al., 2009). The duration of obesity appears contributory with puberty occurring at an earlier age in proportion to earlier age of weight gain (Jasik and Lustig, 2008).

Adipose tissue is one of the key sites of aromatase with increased adiposity leading to increased aromatase activity and thus increased conversion of testosterone to estradiol. Increased adiposity directly reduces SHBG, leading to further increases in free sex steroids (Jasik and Lustig, 2008). Obesity is also associated with reduced hepatic inactivation of estrogen (Schneider et al., 1983). The mechanism of earlier puberty in obese girls thus appears to be increased circulating sex steroids, which stimulate the GnRH pulse generator in the hypothalamus, leading to gonadotroph stimulation in the pituitary and downstream gonadal steroidogenesis (Wagner et al., 2012). Estrogen excess leads to increased growth hormone and insulin-like growth factor 1 which contribute to insulin resistance and hyperinsulinemia and in turn lead to increased adiposity, driving the cycle of obesity and sex hormone production in females (Jasik and Lustig, 2008).

Similarly to adults, the prevalence of overweight and obesity is increasing in childhood (Ogden et al., 2006), and there has been a concomitant advancement of the age of puberty onset suggesting that these two phenomena are linked. An epidemiological study of 156,835 children over a 39-year period found that increased BMI at age seven in both boys and girls predicted earlier age at puberty (Aksglaede et al., 2009). Downstream effects of obesity-related advancements in puberty include reduced final height (De Leonibus et al., 2014), psychological effects of early sexual maturation, and negative consequences, such as increased breast cancer risk, associated with increased lifetime estrogen exposure (Jasik and Lustig, 2008; Wagner et al., 2012).

Female Obesity and Fertility

It is clear that obesity has a negative effect on reproductive fitness, although the relative contribution of ovarian, endometrial and hypothalamic-pituitary factors is contested (Norman et al., 2008). Obesity is associated with increased time to achieve pregnancy, including in patients with regular menstrual cycles (Gesink Law et al., 2007), and greater risk of first trimester miscarriage and recurrent miscarriage (OR 1.2 and 3.5 for obese patients, respectively) (Lashen et al., 2004). Evidence from oocyte donor cohorts has been used to discriminate between ovarian and endometrial factors. Bellver et al. (2007) examined 2656 first ovum donation cycles where the average BMI of the oocyte donor was within the normal range and demonstrated reduced ongoing pregnancy rate per cycle in overweight and obese recipients compared to normal-weight recipients (38.3% vs. 45.5%). Others have examined the BMI of oocyte donors and demonstrated a reduction in clinical pregnancy rates as donor BMI quartile increased, suggesting an effect of obesity on the oocyte as well as the endometrium (Cardozo et al., 2016).

The impact of obesity on oocyte quality is subtle, as there does not appear to be an association between BMI and the rate of aneuploidy in IVF/ICSI cycles performed with preimplantation genetic screening (PGS) (Goldman et al., 2015). This suggests that the increased risk of miscarriage in obese patients does not result from an increased production of aneuploid embryos. This was confirmed in a study which demonstrated miscarriage rates after single euploid embryo transfer in to be lowest in normal-weight women (14.2%), intermediate in overweight women (29.1%) and highest in obese women (41.9%) (Tremellen et al., 2017). Morphokinetic studies of embryo development have similarly not demonstrated a significant difference in cleavage patterns as a result of maternal obesity (Bellver et al., 2013). Follicular fluid from women with obesity may have biochemical changes indicative of metabolic alteration (increased follicular insulin, lactate, triglycerides) and inflammation (C-reactive protein) (Robker et al., 2009). Subtle mitochondrial dysfunction as a result of lipotoxicity may be the cause of diminished oocyte competence (Wu et al., 2015). Another possibility is impaired oocyte-sperm interaction, with some evidence of the negative effects of BMI on fertility being reduced or absent when ICSI is employed (Wang et al., 2016).

Obesity significantly impacts upon IVF cycle treatments and outcomes. Analysis of 239,127 IVF cycles demonstrated decreased implantation rate from 29.5% to 20.3% (normal BMI vs. highest BMI), progressively decreased clinical pregnancy rate to OR of 0.75 in the highest BMI category, and reductions in live birth rate (31% in normal BMI vs. 21% in highest BMI category) (Provost et al., 2016). Obese women were also more likely to have diminished gonadotrophin response, requiring higher doses of FSH and obtaining significantly lower numbers of mature oocytes despite greater utilization of gonadotrophins (Zander-Fox et al., 2012).

Disturbance of the hypothalamic–pituitary–ovarian axis may occur with increasing weight, and anovulatory dysfunction may occur in the context of obesity with or without PCOS. The overall proportion of women who are overweight or obese with PCOS differs according to the population and subpopulation studied, ranging from 14% to 75% (Joham et al., 2016). Conversely, there is a high proportion of reproductive dysfunction in patients presenting with obesity, with 36% of patients submitted to bariatric surgery having a diagnosis of PCOS (Escobar-Morreale et al., 2017). Although not all women with PCOS are overweight or obese, the overlap between the conditions suggests perturbation of shared metabolic pathways, and the term “obesity-associated gonadal dysfunction” has been applied to describe this patient group with PCOS or secondary hypogonadism as a result of excess adiposity (Escobar-Morreale et al., 2014).

Mechanistic theories of the relationship between PCOS and obesity have focused on insulin resistance and the effect of androgens on fat deposition patterns. Patients with androgen excess may have a tendency towards abdominal fat deposition, which aggravates androgen excess and leads to a vicious cycle resulting in the phenotype of PCOS in susceptible individuals (Escobar-Morreale and San Millan, 2007). Alternatively, obesity may be a source of diagnostic confusion due to prolongation of the follicular phase of the menstrual cycle in women with obesity (Dumesic et al., 2015). This is an important clinical distinction as treatment differs between the anovulatory patient with obesity and PCOS and the ovulatory patient with obesity. However, weight loss should be advocated in both patient groups as a primary treatment goal; lifestyle measures should be considered first-line treatments as weight loss of 5%–10% may significantly improve fertility outcomes (Clark et al., 1995). More profound weight loss as achieved with bariatric surgery leads to resolution of PCOS in up to 96% of patients (Escobar-Morreale et al., 2017), and spontaneous pregnancy in 58% of previously infertile women (Milone et al., 2016).

Male Obesity and Fertility

There has been a broad decline in semen parameters over the last 50 years in developed countries and obesity has been cited as a possible contributor (Du Plessis et al., 2010). Epidemiological studies have shown increased odds ratios for infertility in overweight (1.20, 95% CI 1.04–1.38) and obese (1.36, 95% CI 1.13–1.63) men after correction for confounders, including female BMI (Nguyen et al., 2007). Male and female obesity has synergistic effects on fertility in affected couples, which is particularly concerning as spouses of obese individuals are more likely to be obese compared to spouses of normal-weight individuals (Ramlaui-Hansen et al., 2007). A Danish study of 64,167 pregnant women found that subfertility was more frequent when both partners were overweight (1.41, 95% CI: 1.28–1.56) or obese (2.74, 95% CI: 2.27–3.30) compared to normal-weight controls (Ramlaui-Hansen et al., 2007).

The subfertility observed in obese men is largely a consequence of androgen deficiency secondary to increased aromatase resulting in estrogen excess and hypothalamic–pituitary suppression and hyperinsulinemia-associated SHBG reduction. Other mechanisms of obesity-related infertility in men include direct effects on sperm, altered sexual behavior, erectile dysfunction, local heat generation by excess scrotal fat, and oxidative stress which can lead to DNA damage in sperm (Du Plessis et al., 2010). Weight loss via dietary interventions or bariatric surgery improves gonadal and erectile function (Stokes et al., 2015), although the effect is not as robust as in obese anovulatory women (Clark et al., 1995).

Obesity and Pregnancy

Obesity has been documented to affect virtually all antenatal, intrapartum and postnatal complications, with each individual risk increasing with maternal BMI (Grivell et al., 2016). In many nations, the majority of women entering pregnancy are now overweight or obese (Dodd and Thangaratinam, 2016), and there is pressure on health services to optimize perinatal morbidity and mortality outcomes despite increasing maternal weight.

The risk of congenital anomalies is greater in children of overweight or obese mothers, and may be compounded by poor diet quality (Carmichael et al., 2016). The importance of regular folate supplementation in the preconception period should be stressed to all patients, including those with excess body weight. There may be an additional risk of congenital abnormalities in children born to women with a diagnosis of PCOS (Doherty et al., 2015). Detection of morphological abnormalities may be impaired in the fetus of the obese patient and ultrasound evaluation in a tertiary center is recommended.

Medical complications of pregnancy including gestational hypertension, pre-eclampsia, gestational diabetes and thromboembolic disorders, have all been strongly associated with overweight and obesity. In addition to pregnancy-related medical complications, women may present with pre-existing medical complications of obesity which may be compounded by pregnancy (Grivell et al., 2016).

Obesity is a risk factor for preterm birth, and a recent meta-analysis found that preterm delivery was increased in obese patients, possibly as a result of greater burden of medical complications during pregnancy (Faucher et al., 2016). There may also be an association between lower socioeconomic status, obesity and preterm birth. Stillbirth and neonatal death are both strongly linked to pre-pregnancy BMI, with an odds ratio for infant death of 1.42 (95% CI 1.24–1.63) for women in the obese BMI range compared to women in the normal BMI range prior to pregnancy (Meehan et al., 2014). The risk of neonatal death increases with increasing BMI, and appears to be independent of the demographic and medical risk factors which may confound these results (Declercq et al., 2016).

Induction of labor, instrumental delivery, shoulder dystocia and Caesarean section are all more common in overweight or obese women. There is some evidence to suggest that a policy of elective induction of labor at 37 weeks and 39 weeks gestation in patients with a pre-pregnancy BMI $> 30 \text{ kg/m}^2$ may decrease the risk of Caesarean delivery and fetal macrosomia without increasing the risk of other adverse outcomes (Lee et al., 2016). High birthweight (> 4.0 or 4.5 kg , or $> 90\text{th}$ centile using growth charts) is more common in neonates born to overweight or obese mothers and is associated with a greater risk of early infant and childhood obesity. Lifestyle interventions to reduce gestational weight gain failed to mitigate this negative impact on neonatal body composition in a randomized controlled trial (Dodd et al., 2016).

Given the limited effect of pregnancy-based interventions (Muktabhant et al., 2015), it seems reasonable to focus efforts on the pre-pregnancy period and weight loss strategies should be at the forefront of any interaction with a patient before, during or after pregnancy (Dodd and Thangaratinam, 2016; Dodd et al., 2016). A small increase in BMI between pregnancies may lead to a significant increase in obstetric complications including stillbirth in subsequent pregnancies (Cnattingius and Villamor, 2016). The inter-pregnancy interval is emerging as a key treatment opportunity to reduce weight gain and optimize health prior to subsequent pregnancies.

Obesity and Menopause

Obesity prevalence is highest in the years following menopause. Data from 11,247 Australians showed that waist circumference in women was greatest in the 64–74 years age bracket whilst the prevalence of BMI $> 30 \text{ kg/m}^2$ was greatest in women aged 55–74 years (Teede et al., 2010). Menopause is often considered to be a critical time of weight gain with higher BMI seen in perimenopausal and postmenopausal women compared to premenopausal women, independent of age effects (Pasquali et al., 1994). Sex steroid deficiency appears to mediate the observed anthropometric changes during menopause as a placebo-controlled, cross-over study of combined estrogen–progesterone hormone replacement therapy (HRT) found that HRT increased lean body mass, and decreased total fat mass and abdominal fat (Sorensen et al., 2001). A Swedish prospective study of 1462 women starting in the 1960s found that menopause was not associated with an increase in total body weight, but postmenopausal status was associated with increased waist circumference and reduced waist–hip ratio and estrogen replacement postponed these changes (Bjorkelund et al., 1996). Overall, menopause is associated with a typical weight gain of 2–2.5 kg over 3 years which is similar to age-matched premenopausal women; however, abdominal adiposity appears to rise specifically at the menopausal transition (Polotsky and Polotsky, 2010; Wing et al., 1991). Regardless of the precise prevalence and causality of obesity at the time of menopause, obese women face greater health risks compared to normal-weight postmenopausal women.

Obesity may exacerbate menopausal symptoms. Though the aromatization of androgens to estrogens in obese women would suggest that obese perimenopausal women are less prone to hot flushes, increased total and subcutaneous abdominal adiposity are in fact associated with higher odds of hot flushes, which may relate to heat insulation by adipose tissue (Thurston et al., 2008). In addition, obesity in postmenopausal women is associated with a 2.2-fold increase in the rate of vaginal discharge and a 3.6-fold increase in the rate of vaginal irritation/itching (Pastore et al., 2004). Obesity compounds the risk of urinary incontinence in postmenopausal women. The association is particularly strong with stress and mixed urinary incontinence but it extends to urge incontinence and overactive bladder syndrome (Hunskaar, 2008). The Program to Reduce Incontinence by Diet and Exercise (PRIDE) study found that intensive lifestyle intervention with a mean weight loss of 8% over 6 months in overweight or obese women more than halved the number of stress incontinence episodes, and there was a trend towards reduced episodes of urge incontinence (Subak et al., 2009).

Obesity may have more sinister health effects in postmenopausal women. Data from the Women's Health Initiative showed that increased BMI is associated with a 1.76 hazard ratio of endometrial cancer when comparing postmenopausal women in the highest and lowest BMI categories (Reeves et al., 2011). Breast cancer risk among postmenopausal women also increases in proportion to BMI. These cancer risks appear to be largely mediated by increased estrogen exposure, particularly free estradiol which is a function of obesity-related reductions in SHBG (Key et al., 2003). Moreover, obese women with endometrial or breast cancer suffer higher all-cause and cancer-related mortality compared to their normal-weight counterparts (Chia et al., 2007; Protani et al., 2010).

Age-dependent weight gain at the time of menopause is associated with increases in blood pressure, total cholesterol, low-density lipoprotein cholesterol, triglycerides and fasting insulin compared to normal-weight women (Wing et al., 1991). In addition, BMI, waist circumference and waist–hip ratio are independently associated with coronary heart disease in both premenopausal and postmenopausal women (Rexrode et al., 1998), but the absolute risk of coronary heart disease is greatest in obese postmenopausal women due to the compounding effects of obesity and age. Menopause may exert an independent effect on cardiovascular risk due to sex hormone changes including estrogen deficiency, however data are conflicting. Estrogen replacement in women undergoing spontaneous, age-appropriate menopause does not afford any cardiovascular protection and may in fact increase the risk of cardiovascular disease (Carr, 2003).

Obesity was originally thought to lower osteoporosis risk because of aromatase-derived estrogen production, SHBG reduction leading to increased free estradiol, positive effects of leptin on bone including enhanced production of osteoblasts, and insulin-mediated IGF1 production which stimulates osteoblast proliferation (Albala et al., 1996; Migliaccio et al., 2011). This was borne out empirically with obese postmenopausal women shown to have significantly higher BMD at both the hip and spine in one study (Albala et al., 1996), but other evidence has been conflicting. Studies defining obesity as increased BMI or body weight tend to find beneficial effects on bone density and fracture risk, whilst studies defining obesity as increased body fat percentage or central

adiposity typically show that obesity predisposes to osteoporosis (Migliaccio et al., 2011). The Global Longitudinal Study of Osteoporosis in Women (GLOW) of 44,534 postmenopausal women found that overall fracture prevalence was similar between obese and non-obese women but obese women were at significantly greater risk of incident ankle and upper leg fractures and a significantly smaller risk of wrist fracture (Compston et al., 2011). Dietary factors may modulate the interaction between weight and bone status. In a 12-month randomized controlled trial of participants with BMI between 23.5 and 29.9 kg/m² including 30 postmenopausal women, weight loss by dietary intervention but not by exercise was associated with significant BMD decreases at the hip and spine compared to controls (Villareal et al., 2006). Regardless of any potential benefit of weight on bone health, the negative consequences of obesity across the reproductive span of women dominate and weight loss should be encouraged in obese women.

Conclusions

The rates of overweight and obesity have now reached epidemic proportions (Mitchell and Shaw, 2015), and are having an effect on health in manifold ways across the reproductive lifespan. Whilst the adverse effects of obesity on reproduction have been well documented, there is still a large body of conflicting evidence with regards to mechanisms and outcomes, including outcomes following different weight loss program options. Nevertheless, it is clear that an effective approach to achieve a normal pre-pregnancy weight will be essential to ensure optimal reproductive and pregnancy outcomes, and limit the trans-generational effects of overweight and obesity.

Menstrual Disorders: The Need for Agreement on Terminologies and Classification of Causes of Abnormal Uterine Bleeding (AUB)

Hilary OD Critchley, The University of Edinburgh, Edinburgh, United Kingdom

Malcolm G Munro, David Geffen School of Medicine at UCLA, Los Angeles, CA, United States

Introduction, Impact, and History of Menstrual Terminologies and Definitions

Menstruation is a fundamental physiological process but for some individuals, and in many cultures and societies is viewed negatively and remains a taboo topic.

The adverse impact of menstruation and menstrual disorders has increased, a circumstance that in large part is due to the increased frequency of menstruation in the developed world. This is a consequence of earlier menarche, an increased access to contraception, and a reduction in parity and associated lactational amenorrhoea. In industrialized nations, women may expect to menstruate perhaps 400 times over their reproductive lifespan compared with as few as 40 times centuries ago, or even now in less industrialized societies. As a result, symptoms related to menstrual function—abnormal uterine bleeding (AUB)—are an increasing area of unmet clinical need for women in the reproductive years.

Heavy menstrual bleeding (HMB) is a common AUB symptom and frequently a debilitating one, affecting as many as a quarter of women of reproductive age (NICE, 2007; Shapley et al., 2004). The symptom of HMB has a significant negative impact on quality of life and imposes a huge socio-economic burden for women affected, their families and healthcare systems, and negatively impacts their productive participation in the workforce and society at large (Bitzer et al., 2015; Frick et al., 2009; Prentice, 1999). A study conducted in the USA reported financial losses of more than \$2000 per patient per annum (year 2009 costs) due to work absence and expenses related to home management (Frick et al., 2009).

Steady depletion of a woman's iron stores is a frequent consequence of HMB, with resulting iron deficiency and, frequently, iron deficiency anemia (IDA) with associated fatigue, and other symptoms that negatively impact health related quality of life (Percy et al., 2017). Leiomyomas (fibroids) are also often associated with the complaint of HMB and their presence may contribute to issues surrounding fertility and pregnancy outcome. Those with large or multiple leiomyomas may experience symptoms related to pressure on surrounding structures such as bowel, vagina, or the urinary bladder. The estimated annual direct costs (surgery, hospital admissions, outpatient visits, and medications) associated with leiomyomas has been reported as between \$4.1 and 9.4 billion (Cardozo et al., 2012). The estimated cost for lost work-hours in the US was estimated to be between \$1.55 and 17.2 billion annually (Cardozo et al., 2012). When costs related to obstetric outcomes attributed to leiomyoma presence were included, the estimated annualized economic impact rose to \$5.9–34.4 billion (Cardozo et al., 2012).

Therapy for the spectrum of causes of AUB in the reproductive years is frequently challenging. Some, such as endometrial polyps and submucous leiomyomas, are best treated with targeted surgical therapy, while others, such as ovulatory disorders, are often successfully managed with hormonal therapy. However, many current hormonal treatments have side effects that result in up to 60% of women seeking treatment with fertility-ending surgical procedures (RCOG, 2014). Consequently, there continues to be an unmet need for acceptable, effective, fertility-preserving medical treatments for HMB, and only delineation of endometrial physiology (Maybin and Critchley, 2015) and the various aberrations that contribute to AUB in the reproductive years will enable future development of personalized medical therapies for affected women.

One of the issues facing clinicians, students, and both basic and clinical investigators has been the lack of a clearly defined set of criteria for describing both normal and abnormal uterine bleeding (AUB) in nonpregnant women of reproductive age. Over the past 100 years or so, >20 descriptions have been employed in clinical practice to describe abnormally heavy and frequent uterine bleeding (Woolcock et al., 2008). These terminologies include, but are not limited to: Menorrhagia; hypermenorrhea; dysfunctional uterine bleeding (DUB); metrorrhagia; meno-metrorrhagia; and polymenorrhea. The word “menorrhagia” (to “burst forth each month”), was initially used in English medical texts by William Cullen, a Professor at the University of Edinburgh in the late 1700s (Woolcock et al., 2008), but the term was never precisely defined.

The term “Dysfunctional uterine bleeding” or DUB has traditionally been used to describe excessive bleeding (heavy, frequent or prolonged) of uterine origin and deemed not to be due to complications of pregnancy, or detectable pelvic pathology or systemic disease. Further, in some circles, “DUB” was subclassified as either ovulatory or anovulatory. This subclassification has implicated either true endometrial dysfunction or disturbance of the hypothalamic-pituitary-ovarian (HPO) axis and thus typically enabled a diagnosis of exclusion. However, as with the symptom of HMB, DUB has been subjected to often subtle but different definitions in the literature (Woolcock et al., 2008). Consequently, the term “DUB” has been interchangeably considered either a symptom, a sign and/or a diagnosis (Fraser et al., 2007a,b).

Hence great confusion has existed over terminologies relating to menstrual bleeding complaints with consequential impacts on patient care (Woolcock et al., 2008). These confusing older terminologies should ideally become obsolete over time.

Why Revised Terminologies and Clear Definitions Assist in Clinical Management, Counseling, and Sharing of Research Findings

The previous assembly of poor definitions surrounding the term AUB, use of confusing terminologies and lack of classification, led to a global initiative to (i) refine language used to describe uterine bleeding complaints, and (ii) to develop a logical classification system of the underlying causes. This process resulted in the development of two systems under the aegis of the Federation Internationale de Gynécologie et Obstétrique, (FIGO). One is a set of terminologies and definitions of normal and AUB in the reproductive years; the second, a classification of potential causes of AUB known by the acronym PALM-COEIN ([Munro et al., 2011](#)).

First was a distinction between chronic AUB in the reproductive years and acute presentations of uterine bleeding. Chronic abnormal uterine bleeding (AUB) was defined as “bleeding from the uterine corpus that is abnormal in frequency, regularity, duration and/or volume that has been present for the majority of the last 6 months” ([Munro et al., 2011](#)). Acute AUB is defined as, “an episode of bleeding in a woman of reproductive age, who is not pregnant, that is of sufficient quantity to require immediate intervention to prevent further blood loss” ([Munro et al., 2011](#)).

Implicit to the successful and effective use of these two FIGO systems is a co-ordinated approach to securing a comprehensive menstrual history, utilizing simple laboratory investigations and performing appropriate imaging techniques. As momentum gathers, this harmonized approach should facilitate clinical care and enhance phenotyping of patients. As a consequence, a more accurate clinical diagnosis and a resulting menu of optimal treatment approaches should be secured. This suggests that most researchers in the field will now be able to compare and contrast their own patient profiles more precisely with those of other researchers than previously ([Woolcock et al., 2008](#)).

Some remain confused about the relationship of the initialism of HMB to AUB. Indeed, HMB represents “excessive menstrual blood loss leading to interference with the physical, emotional, social, and material quality of life of a woman” ([NICE, 2007](#)). Hence, HMB is just one of a range of symptoms which are included under the “umbrella” of AUB symptoms. Reserved for a research setting is a quantitative definition of HMB of blood loss in excess of 80 mL per cycle ([Warner et al., 2004](#)) a volume of blood loss that carries the risk of iron deficiency and anemia because it exceeds the recommended daily iron intake ([Hallberg et al., 1966](#)).

Consequently, and critical to the accurate classification of causes of AUB in the reproductive years, is a detailed menstrual history designed to identify the features of the abnormal bleeding—frequency, regularity, duration, volume, and intermenstrual bleeding—that themselves provide clues to the potential contributors to the clinical problem. With this clinical foundation, appropriate laboratory and uterine imaging techniques are performed to classify the bleeding caused or contributed to by one or more of the PALM-COEIN categories.

Much has been achieved since the initial publication of System 1, the new definitions and descriptions for uterine bleeding in 2007 ([Fraser et al., 2007a,b](#)), and System 2, the PALM-COEIN classification in 2011 ([Munro et al., 2011](#)), to disseminate and share this initiative. FIGO has endorsed and encouraged use of these two systems—new terminologies and definitions ([Fraser et al., 2016](#); [Munro et al., 2011](#)) and the detailed classification of causes: PALM-COEIN ([Madhra et al., 2014](#); [Munro, 2017](#); [Munro et al., 2011](#)). Rational use of the two FIGO systems generally leads to a more focused and precise approach to active management of the presenting symptoms.

The challenge of standardizing assessment tools for measuring outcomes of AUB complaint and management is the current focus of a piece of work being undertaken through the CROWN Initiative (Core Outcomes in Women’s and Newborn Health) where the aim is to address the widespread variation in reporting of women’s health outcomes ([CROWN, 2016](#)).

The Two FIGO Systems

Context

The two FIGO systems that have defined nomenclature and symptoms of abnormal uterine bleeding (AUB) in the reproductive years (System 1), and the PALM-COEIN classification of causes of AUB (System 2), are designed with an objective to facilitate research, education, and provision of optimal clinical care for women with AUB ([Fraser et al., 2016](#); [Munro, 2017](#); [Munro et al., 2011](#)). The development of these two systems has been the output of a globally (six continents represented) collaborative effort involving experts in clinical, translational and bench research and supported by representation from medical societies, journals and regulatory bodies ([Fraser et al., 2016](#); [Munro, 2017](#); [Munro et al., 2011](#)).

Any abnormalities in volume of menstrual blood loss, frequency, regularity and duration were defined as outwith accepted 5th to 95th percentiles by the FIGO Menstrual Disorders Group ([Munro et al., 2011](#)). Further to these definitions of normality, underlying etiologies of AUB should be categorized in a structured manner and aided by the mnemonic PALM-COEIN ([Munro et al., 2011](#)). The acronym “PALM” embodies the structural causes, including polyp, adenomyosis, leiomyoma, and malignancy (and hyperplasia). The second acronym, “COEIN,” includes the nonstructural causes such as coagulopathies, ovulatory dysfunction, endometrial causes, and iatrogenic as well as the not otherwise classified category which includes etiologies such as Caesarean scar defects and vascular malformations.

System 1—Symptoms

Women with AUB in the reproductive years present with one or more of the symptoms defined in FIGO System 1 (Table 1). These include abnormalities in frequency, regularity, duration and volume. The symptom of HMB generally comprises some combination of heavy rate of flow, including significant “gushes” and large “clots” sometimes also lasting a prolonged period. Bleeding (or spotting) between regular menses is called intermenstrual bleeding; when random, a focal lesion is suggested, when cyclical, a hormonal etiology is inferred.

System 2—Classification of Potential Causes of AUB (PALM-COEIN)

The classification categories are designed to facilitate future development of subclassification systems. Importantly it is recognized that any woman may have one or a spectrum of entities that may cause or contribute to AUB (Fig. 1) (Fraser et al., 2016). It is also recognized that definable entities, such as polyps, adenomyosis, and leiomyomas (fibroids), are often asymptomatic and thus may not in fact contribute to the presenting symptom of AUB (Fraser et al., 2016; Munro, 2017; Munro et al., 2011).

The PALM-COEIN classification starts with polyps (AUB-P), which are categorized as either being present or absent (Fraser et al., 2016; Munro, 2017; Munro et al., 2011). Presence of polyps may be ascertained by one or a combination of contrast hysterosonography, typified by the technique of saline infusion sonography (SIS) and hysteroscopic evaluation with or without polypectomy and associated histopathology (Fraser et al., 2016; Munro, 2017; Munro et al., 2011).

Adenomyosis (AUB-A): The criteria for diagnosing adenomyosis have previously relied upon histopathological evaluation of the depth of “endometrial” tissue beneath the endometrial-myometrial interface from the uterus following hysterectomy (Fraser et al., 2016; Munro, 2017; Munro et al., 2011). Currently, imaging with MRI facilitates diagnosis of adenomyosis but this mode of imaging is not accessible to many clinicians globally. Thus, ultrasound criteria for adenomyosis comprise the minimum requirements for assigning an individual the diagnosis of AUB-A (Fraser et al., 2016; Munro, 2017; Munro et al., 2011). A subclassification system for adenomyosis, applicable for AUB-A and other adenomyotic manifestations is currently under development.

Leiomyomas (AUB-L): The primary FIGO classification system reflects only the presence or absence of one or more leiomyomas (fibroids), independent of location, number, and size of leiomyoma (Fraser et al., 2016; Munro, 2017; Munro et al., 2011). These features are ascertained by ultrasound examination in first instance and supported with MRI if available and indicated. In the secondary FIGO classification system, the clinician determines leiomyomas that involve the endometrial cavity, such as submucous (SM) from others (O), as SM lesions are most likely to contribute to AUB (Fraser et al., 2016; Munro, 2017; Munro et al., 2011). This distinction should use either contrast hysterosonography or hysteroscopy to identify and characterize the type of leiomyoma. A tertiary system is discussed below.

Malignancy and premalignant conditions (AUB-M): Should endometrial sampling of women in the reproductive years with the complaint of AUB identify a hyperplastic or malignant process, then the individual is categorized as AUB-M (Fraser et al., 2016; Munro, 2017; Munro et al., 2011). Further subclassification should employ the appropriate WHO or FIGO system gynecological cancer classification systems.

Coagulopathy (systemic disorders of hemostasis; AUB-C): The term coagulopathy embraces the spectrum of systemic disorders of hemostasis, for example, von Willebrand Disease. A coagulopathy may be identifiable in approximately 13% of women with HMB (Fraser et al., 2016; Kadir et al., 1998; Munro et al., 2011). Up to 90% of women with these abnormalities may be identified through taking a careful structured history (Kouides et al., 2005; Munro et al., 2011). Confirmation of the presence of a coagulopathy requires additional testing and includes, for example, measurements of von Willebrand and Ristocetin cofactor, along with other assays of coagulation function (Fraser et al., 2016; Munro, 2017; Munro et al., 2011). It remains unclear how often such

Table 1 FIGO systems for nomenclature and classification of AUB

<i>Clinical dimensions of menstruation and menstrual cycle</i>	<i>Descriptive terms</i>	<i>Normal limits (5th to 95th percentiles)</i>
Frequency of menses (d)	Frequent	<24
	Normal	24–38
	Infrequent	>38

abnormalities may cause or contribute to AUB, and how often they are asymptomatic or only minimally symptomatic biochemical abnormalities (Fraser et al., 2016; Munro, 2017; Munro et al., 2011).

Ovulatory disorders (AUB-O): Ovulatory dysfunction generally presents as a combination of unpredictable bleeding and variable menstrual blood flow, which is often very heavy (HMB; (Fraser et al., 2016; Munro, 2017; Munro et al., 2011)). Commonly, the woman is either not ovulating, or experiences infrequent ovulation. This pattern of ovulation is common during adolescence and in the latter reproductive years, as the menopause approaches. She may experience “luteal out-of-phase” (LOOP) events (Fraser et al., 2016; Hale et al., 2009; Munro et al., 2011). AUB-O is based on 5th to 95th percentiles of population data and the woman should report cycle lengths in the previous 6 months that vary by at least 20 days (Fraser et al., 2016; Munro, 2017; Munro et al., 2011). It is recognized that such a wide range of normal cycle length reflects the fact that many women experience a short or long cycle in a given year, and that a more reflective range (shortest to longest) of 7–9 days more accurately represents the normal range.

Endometrial causes (AUB-E): If AUB is reported in the presence of predictable and cyclical menstruation (suggestive of normal ovulation) and whether the woman describes HMB or IMB, if other definable causes are absent, then the patient is classified as having AUB-E (Fraser et al., 2016; Munro, 2017; Munro et al., 2011). The cause of AUB-E in a given patient is likely one or a combination of primary endometrial disorders. HMB may be associated with perturbation of mechanisms regulating local endometrial hemostasis (Critchley and Maybin, 2011; Fraser et al., 2016; Maybin and Critchley, 2015; Munro et al., 2011). Currently there are no specific tests available for specific diagnosis of a primary endometrial disorder. A diagnosis of AUB-E is assigned to women with normal ovulatory function and by exclusion of other identifiable abnormalities (such as SM leiomyomas) that are likely to contribute to the abnormal bleeding (Fraser et al., 2016; Munro, 2017; Munro et al., 2011). At present, localized endometrial infections (e.g., chlamydia, TB) would also be included in this category.

Iatrogenic causes (AUB-I): Women are described as having AUB-I if unscheduled endometrial bleeding is reported with use of gonadal steroids (e.g., exogenous oestrogens, progestogens, androgens), or gonadal steroid-related therapies (e.g., GnRH agonists, aromatase inhibitors, SERMs, SPRMS) (Fraser et al., 2016; Munro et al., 2011; Percy et al., 2017; Shapley et al., 2004). AUB considered secondary to administration of anticoagulants, such as warfarin or heparin, or systemic therapies that contribute to disorders of ovulation, for example, medications that interfere with dopamine pathways are now included in this category (Fraser et al., 2016; Munro et al., 2011; Percy et al., 2017; Shapley et al., 2004).

AUB that is “not otherwise classified” (AUB-N) includes entities that may or may not contribute to or cause AUB (Fraser et al., 2016; Munro, 2017; Munro et al., 2011). Such entities, for example, include vascular malformations, the uterine isthmocoele, and other entities that are either uncommonly encountered or that are often poorly defined. Together these entities (or future entities) are positioned in this category AUB-N (Fraser et al., 2016; Munro, 2017; Munro et al., 2011).

It is essential that the FIGO terminology and classification publications (Munro et al., 2011) remain living documents that provide an interactive opportunity for international dialogue and debate. These documents will undergo regular (likely triennial) review during each triennial FIGO World Congress when there is the platform for global discussion concerning clinical utility and recommendations.

Subclassifications of Underlying Causes—Reality and Potential; (Improved Research and Management)

It is recognized that these broad classification categories may, and indeed should, be examined in detail, as there may exist ways to stratify the specific disorder in a way that further facilitates research or therapy. This hypothesis would suggest that

“subclassification” systems have utility in informing investigators, clinicians, educators, and patients regarding the potential role of a clinical symptom or diagnosis. Indeed, one such system exists, the FIGO subclassification system for leiomyomas, an approach that was based on a system for submucous myomas originally conceived by (Wamsteker et al., 1993) (Fig. 1). This system allows for the identification of submucous leiomyomas (Types 0, 1, 2, and 3), and distinguishes them from the “O” group (Types 4–8) not known to contribute to AUB, infertility or recurrent pregnancy loss.

Although the leiomyoma subclassification system is the only one currently supported by FIGO, it seems obvious that such an approach is needed for other entities that comprise System 2, the classification of causes of AUB in the reproductive years. For example, we don’t know the impact on uterine bleeding of single versus multiple polyps, or large versus small polyps. Adenomyosis may manifest in a spectrum of symptoms or findings, ranging from a small poorly defined region in the myometrium, to diffuse thickening of the junctional zone. Other possibilities exist as well—there may be different versions of ovulatory disorders and the endometrium may be the source of a spectrum of molecular or infective anomalies that result in symptoms of AUB. The design of a subclassification system for adenomyosis is currently under development; others should follow.

How These FIGO Systems Can Be Used to Assist in Teaching

Any current presentation on FIGO menstrual systems at an international conference raises a number of spontaneous comments and discussion about the effective use of the systems in a range of teaching forums. It seems clear that both systems provide a clear structure where terminologies and definitions assist focus on the likely causes of AUB, resulting in greater clarity in determining required investigations and improved prioritization from the range of potential therapies. This process is often assisted by the use of a standard stylized form in the format of a matrix, logically listing the key symptoms and causes (Fig. 2). The initial focus should be on clarity in defining symptoms, leading to simple categorization of the most likely underlying causes. Such a simple and clear structure did not exist prior to publication of the FIGO PALM-COEIN system (Munro et al., 2011).

Introduction

Uterine fibroids (UFs) are the most common benign tumor which threaten 70%–80% of women during their reproductive age. They are three times more prevalent among African American women than in Caucasian women, with more aggressive and earlier symptoms. The incidence of UFs is influenced by many factors including age, race, body mass index, and family history. In the United States, the annual economic burden of these tumors is estimated to be 34.4 billion dollars ([Cardozo et al., 2012](#)).

Uterine fibroid has many scientific alternative names such as leiomyoma, leiomyomata, myoma or even descriptive one like fireballs. They appear on the muscular wall of the uterus (myometrium layer) with firm spherical growth of different size ranges, from apple seeds to basketball size. Sometimes they can fill the whole uterus cavity and look like pregnancy ([Sue and Sarah, 2009](#)).

Uterine fibroid tissues are nourished and sustained by the uterine arteries and estrogen hormone effect respectively, which explains why fibroids shrink after menopause ([Borahay et al., 2015](#)).

Fibroids may impair fertility through altering the structure of the uterus, making it unsmooth and curvy with subsequent bleeding ([Pritts et al., 2009](#)).

Types of Uterine Fibroids

Uterine fibroids can be classified based on their location to:

1. *Submucosal*: where tumor is protruding through the uterine cavity. Thus, changing the uterus' capability to regulate the menstrual bleeding and leads to heavy and prolonged periods. Conversely, they typically don't cause pain or extra bleeding in between periods. They can also lead to infertility or miscarriages early in a pregnancy.
2. *Intramural*: Tumor is located within the myometrium and typically doesn't lead to heavy bleeding. However, they can grow to the point that they can lead to chronic pressure with subsequent bulk symptoms as frequent urination, difficulty with bowel function, lower back pain, general aching in the pelvis, and pain during sex.
3. *Subserosal*: where tumor is in the outer border of the myometrium.
4. Pedunculated fibroids where the tumor is attached to the outer border of the uterus by a narrow pedicle containing blood vessels ([Pritts et al., 2009](#)) ([Fig. 1](#)).

Why Women Get Fibroids?

There is no single cause of fibroids, yet there are many internal and external factors that can lead to local hormonal imbalance that creates a growth favoring environment ([Fig. 2](#)).

Fig. 1 Types of uterine fibroids.

*These authors contributed equally to this work.

Fig. 2 Risk factors for uterine fibroids.

Hormonal Effects

Fibroid growth is hormonal dependent (both estrogen and progesterone), so women in conditions of high estrogen level exposure are more susceptible to fibroid development; such as in early pregnancy or perimenopause and also hormonal contraceptive use (Borahay et al., 2015).

Genetic Factor

Family history can be a risk factor, daughters of women with UFs history are about three times more likely to develop UFs than the average (Okolo, 2008).

Ethnicity

As previously mentioned, African American women are three to nine times more likely to have UFs than Caucasian women, furthermore, they appear earlier, larger and greater in number (Huyck et al., 2008).

Vitamin D Deficiency

African Americans in particular are at higher risk for vitamin D deficiency (10 times than Caucasians). Black pigmentation in African Americans reduces the absorption of ultraviolet rays from the sun which is crucial for vitamin D biosynthesis. Moreover, decreased milk consumption due to their lactose intolerance diminishes serum levels of vitamin D. Of note, vitamin D may be obtained from dietary sources such as fatty fish, fish oils, fortified foods, and vitamin supplements; but, the main source of vitamin D is still sunlight exposure (Ross et al., 2011). There are factors that affect cutaneous absorption of vitamin D such as the use of sunblock, levels of sunlight exposure (e.g., season, latitude, and time of day), and most importantly skin pigmentation (Brakta et al., 2015).

Obesity

Many studies reported the association between obesity and increased fibroid risk; an association that may be mediated by elevated bioavailable estrogen and/or testosterone associated with obesity (Ciebiera et al., 2016).

Insulin Resistance

Hyperinsulinemia induced by insulin resistance might have a role in the development of uterine fibroids probably by enhancing ovarian hormone secretion or directly promoting myometrial smooth muscle cell proliferation (Wise et al., 2005).

Perimenopause

Women who approach menopause are at the greatest risk for development of uterine fibroids due to exposure to high levels of estrogen (Machado et al., 2013).

Hair Relaxer

Women who used hair relaxers were 1.17 times more likely to have uterine fibroids than those who did not. Uterine fibroids were theorized that endocrine-disrupting chemicals in hair relaxers could enhance a woman's threat to develop uterine fibroids. Hair

relaxer's have endocrine-disrupting phthalates, which often appear on a label as "fragrance" or "perfume." All types of relaxers are known to cause burns and injuries on the scalp, and such injury eases the entry of the chemicals into the body. Phthalates, a group of hormonally-active compounds, can be absorbed through the skin or via inhalation. Phthalates have an estrogenic effect on cells which promote estrogen-dependent fibroid tumors (Wise et al., 2012).

Symptoms of Uterine Fibroids

Generally fibroids do not cause symptoms to all women. Only one in four women with fibroids are symptomatic. Many women ignore symptoms and their lives are miserable. The symptoms depend on the location and size of the fibroid (Pritts et al., 2009) and include (Fig. 3):

1. Heavy painful prolonged menstrual bleeding or even bleeding between the periods which lead to iron deficiency anemia.
2. Firm painful mass located near the middle of the pelvis, which gives a full feeling in the lower abdomen.
3. Severe back pain.
4. Bowel and bladder dysfunction.
5. Reproductive problems such as infertility, multiple miscarriage, or early labor.
6. Pain during intercourse.

Treatment of Uterine Fibroids

The management of uterine fibroids differs significantly based on the woman's age, symptoms, preferences, and her reproductive plans (Doherty et al., 2014). The main goal of medical management is to improve the patient's quality of life by reducing UFs symptoms with minimum adverse effects. Pharmacological treatment may be chosen over a surgical method, especially in patients who would like to avoid risks inherent to surgery or who desire their uterine preservation for future pregnancy or even feminine reasons. However, the side effects accompanied by prolonged treatment with some medications limit the duration of their use. Moreover, a rebound increase in the size of the leiomyomas can be observed after discontinuing some hormonal medical therapy (Doherty et al., 2014) (Fig. 4).

Treatment of Uterine fibroids	
Surgical	I. Hysterectomy II. Myomectomy
Radiological	I. Uterine Artery Embolization II. Magnetic resonance guided focused ultrasound
Pharmacological	I. GnRH agonists II. SPRMs III. Vitamin D supplement IV. Green tea Extract

Fig. 4 Treatment of uterine fibroids.

Pharmacological Treatments

Non-hormonal treatment

COMT inhibitor

Catechol-O-methyl transferase (COMT) is an enzyme that catalyzes local conversion of hydroxylated estrogen metabolites which has antiestrogenic effect to the more estrogenic methylated forms. Fibroids are known to have high levels of COMT and thus are able to promote the growth stimulating effect of estradiol. COMT inhibitor will result in increase 2-hydroxyestradiol level which might help in tumor shrinkage ([Hassan et al., 2011](#)).

Green tea extract

Green tea is a natural product, commonly used by women for multiple purposes. Epigallocatechin gallate (EGCG) is one of the green tea components with an antioxidant, antiinflammatory and antiproliferative effects so might decrease fibroid symptoms ([Doherty et al., 2014](#)).

Vitamin D₃

Studies have demonstrated a lower mean 25-hydroxyvitamin D [25(OH) D₃] concentration in African American females than in Caucasian females aged 20–40 years. Vitamin D is a potent antitumor agent that inhibits leiomyoma cell proliferation and decreases the size of uterine leiomyomas both in vitro and in vivo ([Brakta et al., 2015](#)).

Hormonal medication

Levonorgestrel intrauterine system

The levonorgestrel intrauterine system (LNG-IUS) for example, Mirena[®] has been widely accepted as an effective treatment of heavy menstrual bleeding by reducing menstrual blood loss, increasing hemoglobin, and relieving symptoms by promoting endometrial atrophy ([Machado et al., 2013](#)).

Gonadotropin-releasing hormone analogs (GnRH)

GnRH analogs were approved by the Food and Drug Administration for preoperative controlling of uterine fibroids. GnRH analog treatment induces a menopausal state with low estrogen levels that may result in intolerable postmenopausal like side effects and bone loss. These side effects could be minimized by adding low dose estrogen and progestin. GnRH analog treatment is therefore limited to a maximum of 6 months ([Doherty et al., 2014](#)). GnRH antagonist as cetrorelix was proposed as treatment for uterine fibroid with the advantage of bypassing the initial flare effect accompanied with the agonists, but being expensive with daily dosage requirement limits its use. Recently, Oral GnRH antagonists as Elagolix and Relugolix are being investigated now with promising results.

Selective progesterone receptor modulators

It has been established that progesterone, acting through its progesterone receptors, enhances the proliferative activity of UFs. New compounds that modulate progesterone receptor activity, collectively termed selective progesterone-receptor modulators (SPRMs), could be useful in the treatment of fibroids. Several SPRMs have been investigated including Telapristone, Asoprisnil and most importantly Ulipristal acetate (UPA). The latter one showed promising effects such as rapid amenorrhea induction, shrinkage of tumor, and anemia improvement, currently UPA can be used for both short term preoperative treatment, with superior efficacy as compared to GnRH agonist leuprolide acetate, or even for intermittent long term therapy up to 1 year ([Donnez et al., 2016](#)).

Selective estrogen-receptor modulators

Estrogens are known to stimulate fibroid growth. Antiestrogens, like tamoxifen or raloxifene that block estrogen action, had the prospects for therapeutic activity against fibroids but clinical trials weren't promising and now not considered as possible anti-UF medications ([Borahay et al., 2015](#)).

Aromatase inhibitors (AIs)

AIs are antiestrogens members that block the synthesis of estrogen by blocking the conversion of androgens to estrogen. Two types of AIs are available:

- A. Irreversible steroidal inhibitors, for example, Exemestane, which forms a permanent bond with the aromatase enzyme complex
- B. Nonsteroidal inhibitors, for example, anastrozole and letrozole, which inhibit the enzyme by reversible competition.

In premenopausal women, AIs have been reported to be well tolerated and reduce the symptoms and size of uterine fibroids. General side effects are hypoestrogenic symptoms, such as hot flashes and osteoporosis (bone mineral density loss) ([Doherty et al., 2014](#)).

Non-Surgical Interventions Treatment

Uterine artery embolization (UAE)

UAE is a minimally invasive treatment for uterine fibroids. UAE is a technique where an interventional radiologist block off the arteries that feed the fibroids and results in fibroid shrinkage. UAE presents some advantages over surgical procedures for the

treatment of uterine fibroids such as a shorter hospital stay, lower risk of major complications, and shorter recovery time, yet possibility of fibroid recurrence is still a drawback (Gupta et al., 2014).

Surgical Treatments of Fibroids

Surgical management of uterine fibroid may be required in women with severe pressure symptoms or unresponsiveness to other therapies (medical, UAE) (Stewart et al., 2016). The size and location of the tumor besides the female desire for future fertility both have roles in the choice of the surgical method. Surgical treatment can be either hysterectomy or myomectomy.

Myomectomy

Myomectomy is the surgical removal of tumor from the uterus. Myomectomy therapy has been well established and confirmed to be safe and effective in the uterine-conserving treatment of uterine fibroids. Myomectomy is an alternative to hysterectomy for women who wish to retain their uterus. However, there is a higher risk of bleeding and longer operative time than with hysterectomy and might affect future fertility as well (Jayakrishnan et al., 2013). Fibroids have a 15% recurrence rate especially for patients with multiple UFs and those in the third decade of life. Ten percent of women undergoing a myomectomy will ultimately need hysterectomy within 5–10 years (Radosa et al., 2014).

Hysterectomy

In women who are satisfied with their childbearing, hysterectomy is the choice of a permanent solution for symptomatic fibroids. Hysterectomy is the surgical removal of the uterus, so it remains the definitive surgical intervention for uterine fibroids (Stewart et al., 2016).

Bright Future for Uterine Fibroid Treatments

Many kinds of research and clinical studies are currently being conducted to find more cost effective and efficacious pharmacological alternatives for the treatment of uterine fibroids.

Adenomyosis

Aaron Budden and Jason Abbott, School of Women's and Children's Health UNSW, Sydney, Australia

© 2018 Elsevier Inc. All rights reserved.

Glossary

Extirpative Complete removal or eradication of an organ or tissue.

Multiparous Two or more pregnancies resulting in birth by any means, where the child is >400 g or >20 weeks gestation.

Parity The number of children delivered by a woman by any means where the child is >400 g or >20 weeks gestation.

Adenomyosis is a structural uterine pathology specifically denoted in the FIGO PALM-COIEN classification system for abnormal uterine bleeding (AUB-A). The principle symptoms of the pathology are pelvic pain and heavy menstrual bleeding (HMB) and confirmation of adenomyosis requires histological diagnosis. The prevalence of adenomyosis either in the general community or a subgroup of women with these symptoms has therefore been difficult to accurately assess. As accuracy and availability of medical imaging modalities including transvaginal ultrasound (TVUS) and magnetic resonance imaging (MRI) have become more widely available, there has been an increase in image-based diagnosis with high correlation to histological disease when performed by experts. The debate regarding the accuracy of these imaging techniques, which modality to use, and the classification of disease continues to be important factors in this increasingly recognized uterine pathology.

Epidemiology and Etiology

Diagnosis of adenomyosis may only be truly made after invasive extirpative surgery and complete sectioning, or a positive myometrial biopsy with histological demonstration of endometrium or endometrium-like structures within the myometrium and associated smooth muscle hypertrophy or hyperplasia. Given the difficulty in noninvasive diagnosis, the prevalence of adenomyosis is variably reported from as few as only a few percent of women through to 70%, although many studies suggest a 20%–35% prevalence (Vercellini et al., 1995) when post-hysterectomy specimens are examined histologically.

Increasing parity has been commonly associated with an increased risk of adenomyosis and multiparous women who undergo caesarean delivery are reported to be up to five times more likely to develop adenomyosis, although this association is variably reported within these studies (Vercellini et al., 1995). It is hypothesized that breach of the endometrial junction leads to glandular elements growing within the myometrium, which accounts for the increased association with multiparity as well as women who have received curettage at uterine surgery, termination of pregnancy, and caesarean delivery (Parazzini et al., 1997), although these factors are again variably reported.

Endometriosis is commonly noted in the presence of adenomyosis both during imaging and at the time of surgery. As there are similar pathogenic pathways for both diseases, it has been hypothesized that these diseases may occur on a continuum, although current data to support this is lacking. Other risk factors identified include advancing age and tamoxifen use whilst smoking may be protective (Parazzini et al., 1997).

There are a number of pathophysiological theories thought to contribute to adenomyosis, however as for endometriosis, there are likely multiple factors involved including:

1. Infolding of the endometrium with direct penetration into the myometrium
2. Damage to the endometrial–myometrial interface by pregnancy, myometrial incision, or development of leiomyomas
3. Increasing age with cellular damage and repair and
4. Vascular spread

Recent cell biology studies have demonstrated a genetic role in developing adenomyosis. From a well conducted case-control study, down regulation of DNA methyltransferase 3 alpha (DNMT3A) was reported to be significantly decreased in women with adenomyosis compared to women with eutopic endometrium (Zou et al., 2017) and may be responsible for ectopic endometrial cell proliferation and invasion. From separate work, researchers investigated RhoA and ROCK-I messenger RNA and protein expression, which is responsible for various cellular functions including cell migration and proliferation and normally has cyclical expression in concert with menstrual cycles. In women with adenomyosis, the authors reported higher levels of RhoA and ROCK-I messenger RNA and protein expression throughout the menstrual cycle with loss of normal upregulation and downregulation of protein expression (Wang et al., 2016).

Whilst there are common threads in the aetiological theories of adenomyosis with endometriosis and other benign diseases of the reproductive tract there, the complex epigenetic, hormonal, and reproductive factors are not yet fully defined and continues to be an area of research and progress in this field.

Diagnosis

Whilst histology is considered the ultimate manner by which the diagnosis of adenomyosis may be made, even the variations in the pathological definitions thwart a clear determination of what is 'disease'. The presence of glandular and stromal tissue within the myometrium is generally agreed upon, however, the depth at which this occurs from eutopic endometrium in the absence of a basement membrane is more problematic. Specific pathological problems include angle of specimen sectioning, specimen preparation, and the natural irregularity of the endometrial–myometrial border. In addition, the requirement for endometrium to be connected directly to the basalis is fiercely debated since isolated cystic lesions deep in the myometrium, separate to the endometrium, are well recorded. These difficulties have led to a number of reported definitions which are based on boundary disruption, depth of penetration, and distribution within the uterus.

It should be clear from the aforementioned problems, that these histological definitions require the uterus to be removed—a fact that is not acceptable for women who desire current or future fertility. Less invasive methods assessing histology through specific biopsy tools are reported however they each have potential specimen collection and diagnostic issues. For example, given that a biopsy may only sample part of the uterine muscle, this is problematic for accurate histological diagnosis. A small prospective study compared TVUS alone versus TVUS guided needle biopsy prior to performing a hysterectomy and reported adenomyosis in 29/102 (28%) of those women (Vercellini et al., 1998). The sensitivity for TVUS was 83% and just 45% for biopsy with a specificity of 67% and 96% respectively. In a large cross-sectional study involving 292 women examining the use of hysteroscopic biopsy (Dakhly et al., 2016), diagnosis by inspection of the endometrial cavity had a sensitivity of 41% and the endomyometrial biopsy had a sensitivity of 54% compared to the TVUS with a sensitivity of 84%. Specificity of these instruments was 47%, 54%, and 60% respectively.

The diagnostic capabilities of magnetic resonance imaging (MRI) have evolved substantially and are now able to differentiate three distinct layers of the functional zone between the endometrium and myometrium. Thickening of the junctional zone to > 12 mm is a reported surrogate diagnostic marker of adenomyosis on MRI or 3D ultrasound, however the normal physiological change that occurs in the zone with the menstrual cycle has limited its interpretation and variations in both this thickness and this finding in isolation as truly representative of disease continued to be debated.

Ultrasound and MRI

With an increasing desire for uterine retention and improvement in imaging techniques, noninvasive diagnosis of adenomyosis has received greater attention and study. The Morphological Uterus Sonographic Assessment (MUSA) Group reported a consensus statement describing the terms, definitions and measurements that may be used in the sonographic description of uterine diseases including adenomyosis (Van den Bosch et al., 2015). The authors state that ultrasound of the myometrium may be performed using a transabdominal (TAS) or transvaginal (TVS) approach though the resolution of TVS is preferred as it allows for detailed assessment of the myometrium. When assessing the myometrium, the authors recommend measuring the uterine corpus separate to the entire length of the uterus (corpus and cervix) and the fundal length (fundal serosal surface to the fundal tip of the endometrial cavity) and endometrial cavity (fundal tip of the endometrial cavity to the internal os) should also be measured separately. Serosal contour should be reported as either regular or lobulated, the myometrial walls reported as symmetrical or asymmetrical, and the overall echogenicity as homogenous or heterogeneous. If a lesion is visualized it should be described as well-defined or ill-defined and its location specific as well as the ratio of the thickness of the lesion to the uterine wall thickness measured on the same image. Finally the presence or absence of cysts should be reported and where present the number, maximum diameter, and appearance of cyst fluid included.

When evaluating the use of imaging techniques in the diagnosis of adenomyosis, the changes in imaging technology and techniques must be considered. Older studies reported poor diagnostic accuracy of adenomyosis at sonography however with changes in 2D transvaginal ultrasound technology, diagnostic accuracy has improved and more recent studies conducted using expert sonologists and well-defined criteria report very high accuracy (Luciano et al., 2013; Exacoustos et al., 2011). In a prospective study involving 54 symptomatic women scheduled for hysterectomy, 3D ultrasound mapping was undertaken prior to taking full thickness serosa to endometrium biopsies from areas suspected of adenomyosis (Luciano et al., 2013). This resulted in a sensitivity of 92% and a specificity of 83% when compared to histology after hysterectomy. Importantly from this study, women who had previous endometrial ablation or were receiving medical treatment had substantial reductions in diagnostic accuracy reflecting the changes in the endometrial myometrial interface that may occur in these circumstances.

In another small prospective evaluation of women, 2D and 3D TVUS was performed prior to hysterectomy and histological diagnosis (Exacoustos et al., 2011). The presence of myometrial cysts was the most specific 2D TVUS feature and a heterogeneous myometrium was the most sensitive. For 2D TVUS and 3D TVUS, respectively, the sensitivity was 75% and 91%, the specificity was 90% and 88%. It must be recognized that these data occurred in studies with strict methodology but it demonstrates what the best possible accuracy is in the noninvasive diagnosis of adenomyosis.

The increased access to MRI and its relatively less dependence on operator experience has led to considerable investigation in its diagnostic capabilities of adenomyosis. MRI has been compared to ultrasound in a number of studies, again with changes in the diagnostic accuracy over time of both modalities. From a meta-analysis published in 2010, 2312 women from 23 studies examining ultrasound and MRI concluded that both techniques have a high accuracy for the noninvasive diagnosis of

adenomyosis, although MRI was determined to more often result in the correct diagnosis ([Champaneria et al., 2010](#)). The pooled sensitivity of ultrasound from this assessment was 72% and specificity 81% compared to MRI with a sensitivity of 77% and specificity of 89%.

With improvement in imaging technology and more reliable interpretation of findings from images, data support a high accuracy for the noninvasive diagnosis of adenomyosis with either ultrasonography or MRI. Whilst MRI may be more accessible than previously, it continues to be both more expensive and less available than transvaginal ultrasound and this may be driving factors in the choice of imaging for women with suspected adenomyosis.

Symptoms

A woman's clinical presentation is the usual starting point for a differential diagnosis list and therefore remains an essential part of the clinical process. However, the reliance of the clinical symptoms usually associated with the presentation of suspected adenomyosis is neither sensitive nor specific. Broadly speaking, abnormal uterine bleeding (AUB), pelvic pain (dysmenorrhoea and noncyclical pelvic pain), and infertility are three main symptoms that women with adenomyosis may present with to their care provider.

Heavy menstrual bleeding (HMB) does not appear to be highly predictive for all forms of adenomyosis, although increasing severity of disease may increase the likelihood of this symptom. Likewise, dysmenorrhoea and other noncyclical pelvic pain present in a variety of gynecological conditions and there is no evidence about pain quality or site that differentiates it from other conditions such as endometriosis or leiomyomas.

Adenomyosis is increasingly being diagnosed during investigations of the subfertile or infertile couple. MRI studies in women with adenomyosis have demonstrated uterotubal disturbance and substantial dysperistalsis when diffuse forms of the disease occur. Increased symptoms such as dysmenorrhoea may represent worsening of these disorganized contractions of the reproductive musculature and may contribute to poorer sperm transportation for spontaneous pregnancy and increased implantation failure for advanced reproductive technology (ART) cycles ([Vercellini et al., 2014](#)).

Biomarkers

Despite general advancement in the field of cellular biology and the use of specific biomarkers for diagnostics, studies of potential biomarkers for adenomyosis have been limited. Many of the biomarkers being studied are linked to etiology and are nonspecific, leading to issues in terms of differentiation from both gynecological disease and other systemic disease.

One of the more promising biomarkers for diagnosis of adenomyosis is MALDI-TOF-MS which has been associated with both adenomyosis and endometriosis but unfortunately does not differentiate between these diseases ([Long et al., 2013](#)). Another promising biomarker is Moesin, a protein overexpressed in adenomyosis and whilst it is still being developed there is a potential for determine the extent of disease within the myometrium ([Ohara et al., 2014](#)).

Given the current issues with utility of biomarkers for the diagnosis of adenomyosis, none are currently in use clinically and should only be examined in the framework of appropriate clinical research studies.

Classification

Most classification systems for adenomyosis to date have relied on histopathological assessment of the uterus with or without imaging criteria. In part due to an increased desire to diagnose women without performing extirpative surgery, there has been a call for a standardized classification system to aid in diagnosis and management. Previous reviews, studies and consensus meetings have proposed several systems to improve clinical and research descriptions although not as yet has been universally adopted ([Grimbizis et al., 2014](#)). One of the problems of these classification systems is the primary focus on histological findings, specifically relating to depth and/or severity of disease. One small study has reported a classification based on MRI appearance however of the 163 women included only 40 underwent hysterectomy for complete histological comparison ([Kishi et al., 2012](#)). The main classification systems are presented in [Table 1](#).

Treatment

Women suffering from AUB and dysmenorrhoea have commonly been managed with extirpative surgery with adenomyosis diagnosed retrospectively based on histopathological findings. As previously discussed, this method of treatment is not ideal to every woman and available management strategies will depend on specific symptoms, for example dysmenorrhoea or noncyclical pelvic pain, AUB or infertility as well as the desire for current or future fertility. As both the understanding of the disease and diagnosis has improved, the available treatment options has improved and includes medical treatments, surgical options, radiologic or sonographic interventions or combinations of these choices.

Table 1 Classification systems for adenomyosis

Depth	Severity	Other histopathology	MRI
Siegler and Camilien (1994) ^a Grade 1: inner 1/3rd Grade 2: 2/3rd of myometrium Grade 3: entire myometrium	Siegler and Camilien (1994) ^a <i>Mild:</i> 1–3 islets on low powered field (LPF) <i>Moderate:</i> 4–9 islets <i>Severe:</i> > 10 islets Hulka et al. (2002) <i>Mild:</i> microscopic foci present or only inner 1/3 involved <i>Focal:</i> focal adenomyosis <i>Severe</i>	Grimbizis et al. (2014) <i>Diffuse:</i> extensive disease with endometrial mucosa scattered throughout uterine musculature <i>Focal:</i> Hypertrophic and distorted endometrium within the myometrium <i>Polypoid:</i> circumscribed masses of glands and stroma that is predominantly smooth muscle <i>Other:</i> endocervical type and retroperitoneal forms	Kishi et al. (2012) <i>Type I:</i> adenomyosis affects only the inner layer of the myometrium and not other areas <i>Type II:</i> adenomyosis affects only the outer layer of the myometrium <i>Type III:</i> isolated adenomyomas without a relationship to other structural components <i>Type IV:</i> any other variation that does not satisfy these variations
Sammour et al. (2002) 1. < 25% 2. 25–50% 3. 51–75% 4. > 75% of myometrial thickness <i>Penetration ratio:</i> depth of penetration to myometrial thickness	Vercellini et al. (2006) ^b <i>Grade 1:</i> 1–3 islets at LPF <i>Grade 2:</i> 4–10 islets <i>Grade 3:</i> > 10 islets	Vercellini et al. (2006) ^b <i>Configuration of lesion:</i> 1. Focal 2. Nodular Diffuse	
Vercellini et al. (2006) ^b <i>Mild:</i> < 1/3 deep <i>Moderate:</i> 1–2/3rd deep <i>Severe:</i> > 2/3rd			

^aSystem includes both depth and severity.^bSystem include depth, severity, and configuration (other).

Medical Treatment

Medical options are often first line treatments and are of particular benefit where women desire uterine conservation to allow for pregnancy to occur. Options include:

1. Nonhormonal medical to control symptoms of AUB and pain
2. Oral hormonal control such as a combined oral contraceptive pill, oral progestins, GnRHa, danazol, and aromatase inhibitors
3. Intrauterine progestin

In women who complain of symptoms of heavy menstrual bleeding (HMB) are commonly offered options that include nonsteroidal anti-inflammatories, antifibrinolytic agents, and/or the combined oral contraceptive pill. Whilst these agents may be successful to reduce symptoms of HMB in some forms of AUB, there few data to support adenomyosis (AUB-A) specific outcomes for these options. In comparison, pharmacological agents used to suppressed endometrial growth including GnRHa, danazol, oral progestins and aromatase inhibitors are reported to be efficacious for the treatment of adenomyosis (Fawzy and Mesbah, 2015). These agents have also been shown to be efficacious in women with adenomyosis and infertility, although numbers of women involved in high quality studies are few and comparative data are lacking at this time. When considering these agents for HMB or infertility, the benefit of such medication versus the potential side effects must be evaluated carefully as the side effects may be equally unacceptable to the woman compared to the systems experienced by adenomyosis.

The use of the Levonogestrel intrauterine device (LNG-IUD) has received the most attention in studies examining the efficacy of medication to reduce symptoms of AUB and pain in women with adenomyosis. In a recent randomized controlled trial (RCT) 75 women who received either the LNG-IUD or hysterectomy (Ozdegirmenci et al., 2011) were assessed for changes in quality of life (QOL) over 1 year. The authors reported LNG-IUD improved hemoglobin levels of the first 6 months compared to hysterectomy and had a superior effect in the psychological and social life domains of the QOL scores. This has supported previous cohort studies which demonstrated improvement in dysmenorrhoea and high rates of satisfaction.

Surgical Treatment

Surgical management for adenomyosis may be:

1. “Definitive” or “curative” where hysterectomy is performed. Whilst hysterectomy resolves adenomyosis and its associated symptoms of HMB and pain, it is a major surgery and is not appropriate in women wanting future fertility or to maintain their uterus.
2. Conservative excisional surgery where the intent is to maintain the uterus in an intact and functional capacity with the aim for future fertility.
3. Conservative ablative surgery where there is no intent of fertility (and pregnancy would then be contra-indicated).

One of the difficulties commonly faced when considering surgical options is understanding the depth and extent of disease and what type of surgery could reasonably give symptomatic benefit. When considering conservative excisional surgery it is extremely important to perform reliable imaging studies to facilitate informed discussion with the patient regarding outcomes and expectations in addition to accurate preoperative planning. Fertility sparing surgery may be accomplished by:

- Hysteroscopic endomyometrial resection
- Local hysteroscopic resection
- Local laparoscopic resection
- Laparoscopic or ultrasound directed radiofrequency ablation

Hysteroscopic endomyometrial resection requires a high degree of skill and excellent preoperative imaging. Where clinical settings offer such expertise this procedure is reported to be successful with one prospective study reporting good outcomes with superficial adenomyosis. Unfortunately, in women with deep disease, the procedure had much higher failure rates to achieve improvement in symptoms. A recent meta-analysis of 1049 women which evaluated women undergoing hysteroscopic resection, in those where complete surgical removal of disease was reported there was a reduction of dysmenorrhea of 82%, HMB reduction of 69%, and a postoperative pregnancy rate of 60%. Where only partial excision was possible, these results are all reduced at 82%, 50%, and 47% respectively (Grimbizis et al., 2014). A particular challenge with these procedures is intraoperative heavy bleeding leading to increased operating time and decreased resection rates. As such, adjuvant procedures such as temporary uterine artery occlusion or preoperative GnRHa have been suggested to facilitate the procedure however there is currently insufficient evidence to support these approaches.

Similar to hysteroscopic resection, a laparoscopic approach aims to resect local disease whilst retaining a functional uterine corpus but likewise requires a high degree of skill. Most recently a retrospective study of 179 women who underwent laparoscopic uterine artery occlusions and resection of adenomyosis (Liu et al., 2014) reported uterine volume reduction of 58% at 3 years and a significant improvement in QOL scores. This is consistent with older and smaller studies and suggests there is some benefit to this approach.

Radiologic or Sonographic Interventions as Treatment

In alignment with the development of treatment delivery using interventional radiology in a wide range of diseases, there is increased interest in these procedures to deliver a nonsurgical option for women with adenomyosis. Evidence on techniques remain largely retrospective, with few prospective trials and two randomized controlled trials that report on specific adjuvant treatments to the principal intervention rather than comparing between techniques. Currently these techniques are too diverse to compare directly and known studies are summarized in Table 2.

Table 2 Sonographic and interventional radiological techniques for treating adenomyosis

<i>Authors and year</i>	<i>Methodology</i>	<i>Outcome(s)</i>
Kim et al. (2011)	Retrospective cohort study 35 women with symptomatic adenomyosis treated with magnetic resonance guided focused ultrasound (MRfFUS)	Significant improvement in QOL scores at 6 months
Liang et al. (2012)	Retrospective cohort 17 women with symptomatic adenomyosis treated by UAE	Reduction in dysmenorrhoea in 75% of women at 6 months Resolution of pain in 56% Mean reduction in uterine volume of 50%
Smeets et al. (2012)	Retrospective cohort 40 women with symptomatic adenomyosis treated by UAE	Significant improvement in QOL in 72% at 5 years Hysterectomy in 18% for ongoing symptoms
Long et al. (2015)	Prospective study 47 women with symptomatic adenomyosis and uterine volumes greater than 200 cm ³ treated by USgHIFU	Significant reduction in uterine volume Significant reduction in dysmenorrhoea at 12 months and improvement in QOL
Chen et al. (2015)	Retrospective cohort 2549 women with symptomatic adenomyosis treated by USgHIFU	95% of women had successful treatment Mean volume ablation rate 73% 10% adverse outcome (majority were minor-abdominal pain, vaginal discharge)
Ferrari et al. (2016)	Prospective trial 18 women with symptomatic adenomyosis treated by MRgFUS — 7 women with diffuse disease — 11 women with focal disease	There was a reduction in uterine volume for most women 83% of women had a junctional zone thickness of < 12 mm at 1 year post-treatment
Hai et al. (2017)	Prospective trial 87 women with symptomatic adenomyosis treated by TVUS guided transcervical radiofrequency ablation	Mean volume reduction 40.8% at 6 months, 41.2% at 12 months. Dysmenorrhoea statistically declined 2 women with intrauterine adhesions

Infertility and Reproduction

The impact of adenomyosis on female infertility and reproduction is becoming increasingly appreciated. The symptomatic management of women with AUB and pain who wish to conserve fertility has been outlined above however there is evidence to suggest the disease may impact on spontaneous pregnancy and ART efficacy as well as possible complication of pregnancy.

The possible association of adenomyosis to infertility continues to be debated. Whilst transvaginal Imaging studies have shown an increased spontaneous miscarriage rate in women with diffusely enlarged uterus but without distinct uterine masses this it did not affect the pregnancy rate. In contrast, a current meta-analysis review of women with adenomyosis undergoing IVF demonstrated a lower clinical pregnancy rate in women with adenomyosis (40.5% vs. 49.8%) (Vercellini et al., 2014) though there was significant heterogeneity between studies. This review also reported on higher miscarriage rate among women with adenomyosis (32% vs. 14%). Subsequent to this systematic review, studies continue to report on clinical pregnancy rates in women with adenomyosis undergoing IVF however the most important outcome, live birth rate, still remains under reported.

In women who are able to conceive there are several studies that report increased complications of pregnancy in women with adenomyosis. From a large case-control study of 2138 women, those diagnosed with adenomyosis were more likely to have premature delivery (OR 1.84) or premature rupture of membranes (OR 1.98) (Juang et al., 2007).

Congenital Uterine Abnormalities

Pedro Aci n and Maribel Aci n, Miguel Hern ndez University of Elche, Alicante, Spain; and Institute of Gynecology P.A.A, Alicante, Spain

  2018 Elsevier Inc. All rights reserved.

The congenital anomalies affecting the development and morphology of the fallopian tubes, uterus, vagina and vulva, with or without associated ovarian, urinary, skeletal or other organs anomalies, are included within the broad spectrum of female genital tract malformations. The majority of them affect the uterus (fused M llerian ducts) and are therefore reported as uterine or M llerian malformations, which have an influence on the reproductive processes. But we should not forget that many anomalies affecting the M ller ducts may have their origin in a mesonephric (Wolff ducts) or gubernaculum anomaly, being then, in the first case, associated to other genital and extragenital malformations. In fact, the mesonephric anomalies are more complex and present a difficult diagnosis and treatment (Ac n and Ac n, 2016a).

Uterine malformations have been reported to occur in 3%–4% of women overall, in 4% of infertile women and in 15% of those who have experienced recurrent miscarriage (Ac n, 1997; Raga et al., 1997). Other studies that have evaluated the prevalence and diagnosis of congenital uterine anomalies in women with reproductive failure (Saravolos et al., 2008) observed higher percentages: 6.7% in the general population, 7.3% in the infertile population, and 16.7% in the recurrent miscarriage patients. Therefore, common uterine anomalies (M llerian) are frequent and important because of their effects on fertility. Mesonephric anomalies, certain obstructive M llerian malformations and other malformative combinations are particularly important because they cause several clinical symptoms, especially gynecological in young women, and impact the patient's quality of life, in addition to creating fertility problems. Such complex malformations of the female genital tract are not that common (17.3% of all female genitourinary malformations).

Etiology

The etiology of most uterine malformations is generally believed to be multifactorial. In general there is no evident cause or association. The few existing studies have identified a degree of risk for siblings that is similar to most other multifactorial disorders (Jacquinet et al., 2016). The karyotype is generally normal but sometimes there are mosaicisms or other anomalies that do not seem related to the malformation; some familial cases seem to be linked to a recessive autosomal gene and others to a dominant autosomal one, but to date, only a few genes (HNF1B, WNT4, WNT7A, HOXA13) have garnered strong evidence of causality, mainly in syndromic presentations; and the sequencing of candidate genes in series of individuals with isolated uterine abnormalities has been able to suggest an association for several genes, but confirmation of a strong causative effect is still lacking for the majority of them (Jacquinet et al., 2016). And the environmental causes can only explain some cases. Apart from the diethylstilbestrol exposure-related (DES) syndrome, other teratogenic drugs, malnutrition, metabolic alterations, viral infections and placental anomalies have been implied. Numerous reports of discordant phenotypes in monozygotic twins (e.g., Mayer–Rokitansky–Kuster–Hauser (MRKH) syndrome vs. normal uterus) argue against strong heritability and suggest that post-zygotic somatic mutations or non-genetic mechanisms such as epigenetic or microenvironmental factors underlie the occurrence of congenital uterine malformations (Milsom et al., 2015; Rall et al., 2015; Jacquinet et al., 2016). However, whereas these mechanisms may explain sporadic cases, reports of familial cases do support the existence of a predisposing genetic background that may be stronger in some families compared to others (Jacquinet et al., 2016). According to Hammoud et al. (2008), approximately 10% of cases of M llerian anomalies seem to be attributable to a familial association. They conclude that M llerian anomalies have a strong familial aggregation and follow a polygenic and multifactorial inheritance.

Nevertheless, the familial association is difficult to research. Uterine ultrasounds have not usually been performed, or not performed in extended family members with asymptomatic or subtle anomalies. But also, although in many families recurrences tend to recapitulate the same type of uterine malformation, recurrences with variable types of uterine maldevelopment have also been reported in several families suggesting that similar genetic background could still predispose to different types of uterine malformation with variable penetrance and expressivity (Jacquinet et al., 2016).

Thus, it seems then that genital malformations are influenced by multifactorial, polygenic and familiar mechanisms that together can create a favorable environment for the anomaly, but in most cases there is no evident cause or association. However, the embryological development of the genital tract and the chain of anatomical events leading to the production of the malformation are better known, and therefore, we must know the embryology for a better understanding of the pathogenesis.

Embryology

Fig. 1 shows a scheme of female genito-urinary embryology. Briefly, a longitudinal invagination of the coelomic epithelium is formed on the outer side of the urogenital ridge and originates the paramesonephric or M llerian duct. This duct opens into the celomic cavity at the top and descends in parallel and externally to the mesonephric duct. Then, both M ller's ducts cross ventrally the mesonephric ducts, growing in the caudomedial direction until fusing into a Y-shaped middle structure that forms the uterine

Fig. 1 Embryology of the female genito-urinary tract (frontal view). The formation of the uterine primordium and the opening of the mesonephric ducts into the urogenital sinus are shown. Müllerian tubercle can be seen between both Wolffian ducts and the ureteral buds sprouting from the opening of the Wolffian duct into the urogenital sinus. MD, Müllerian ducts; WD, wolffian ducts; K, kidney; MT, Müllerian tubercle; US, urogenital sinus.

primordium. Thus, it is well known that the uterus is formed from the fused caudal portions of the Müller ducts. However, nowadays we also know that: (1) the appropriate development, fusion and reabsorption of the separating wall between both Müller ducts is induced by the Wolffian ducts placed at both sides and which act as guide elements. (2) The fused Müller ducts form the uterus until the external cervical os, and the inducing mesonephric ducts regress cranially though they enlarge caudally from the level of cervical os, form the sinuvaginal bulbs, incorporate the Müller tubercle's cells and give rise to the vaginal plate whose cavitation is covered by Müllerian cells with a cuboidal or paramesonephric epithelium. Then, by metaplastic induction or by epidermization from the sinus, the vagina is covered by a flat, squamous, stratified epithelium. (3) Since the ureteral bud sprouts from the opening of the wolffian duct into the urogenital sinus, the absence or distal injury of one of these ducts will give rise to a renal agenesis and blind or ipsilateral athretic hemivagina and a uterine anomaly (fusion or reabsorption defect) due to a failure in the inducing function of the injured mesonephric duct. (4) In the absence of formation and caudal growth of the urogenital wedge, there is persistent urogenital sinus and then the opening of the vagina into the sinus can be seen as a vesicovaginal fistula just underneath and between both urethral orifices (Martínez-Escoriza et al., 2011). (5) The female gubernaculum is likely formed by muscle fibers that are not of a mesonephric or paramesonephric origin and their attachment to the Müllerian ducts allows or induces the fusion and adequate development of the uterus. Thus, dysfunction of the female gubernaculum probably results in female genital tract malformations (Acién et al., 2011).

The interaction and correspondence between the analyzed embryonic structures and its normal or abnormal adult derivatives can be seen in Acién et al. (2010c).

Classification

Based on the Müllerian development processes, we should consider the classification of the uterine or Müllerian malformations as shown in Table 1. This classification system for uterine or Müllerian malformations corresponds to the traditional classifications

Table 1 Classification of the uterine or Müllerian malformations

-
1. Anomalies caused by total or partial agenesis:
 - (a) Of both Müllerian ducts: Mayer–Rokitansky–Kuster–Hauser (MRKH) or Rokitansky syndrome, or
 - (b) Müllerian agenesis of just one side: unicornuate uterus
 2. Anomalies caused by total or partial absence of fusion:
 - (a) Didelphys uterus and
 - (b) Bicornuate uterus–bicornis-bicollis and bicornis-unicollis uteri
 3. Anomalies caused by total or partial absence of reabsorption of the septum between the Müllerian ducts:
 - (a) Septate and subseptate uterus
 - (b) Arcuate uterus (minimum subseptate or bicornuate uterus?)
 4. Anomalies caused by a lack of later development:
 - (a) Hypoplastic uterus, T-shaped, and
 - (b) Diethylstilbestrol exposure [DES] syndrome, DES-related uterus
-

(Jarcho, 1946), the widely used [American Fertility Society AFS/ASRM classification \(1988\)](#) or that included in Netter's Atlas (1979). The [AFS/ASRM \(1988\)](#) considered seven basic groups that are analyzed basically from the point of view of the Müllerian development and their relationship to fertility: (I) agenesis and hypoplasias; (II) unicornuate uteri; (III) didelphic uteri; (IV) bicornuate uteri; (V) septate uteri; (VI) arcuate uteri; and (VII) anomalies related to DES syndrome. The additional findings referred to the vagina, cervix, fallopian tubes, ovaries and urinary system must be pointed out apart.

The latest ESHRE/ESGE classification system “uterus-cervix-vagina, UCV” ([Grimbizis et al., 2013](#)) is also based on those concepts (Müllerian development processes), with anatomy providing the basis for the systematic categorization of anomalies. The main types of uterine anomaly are: U0, normal uterus; U1, dysmorphic uterus (T-shaped, infantilis, others); U2, septate uterus (partial, complete); U3, bicorporeal uterus (partial, complete and bicorporeal septate); U4, hemi-uterus (with or without rudimentary cavity, communicating or not horn); U5, aplastic (with or without rudimentary cavity); and U6, unclassified malformations.

However, these classification schemes essentially refer to only Müllerian anomalies or the anatomic visual appearance and do not explain or suggest the actual origin of female genitourinary tract malformations nor their appropriate therapeutic correction. We, based on the embryology presented before, proposed an embryological-clinical classification that was revised and updated in [Acien and Acien \(2011\)](#) including six groups of female genitourinary malformations (see [Table 2](#)). In latter works ([Acien and Acien \(2016a,b\)](#)) we have analyzed the correspondence between the embryological-clinical classification, the [AFS/ASRM \(1988\)](#) and the recent ESHRE/ESGE ([Grimbizis et al., 2013](#)). As expected, the embryological and clinical classification correlates better between vaginal anomaly, uterine anomaly, and ipsilateral renal agenesis or renal dysplasia with or without ectopic ureter, suggesting the origin and possible clinical presentation and thus leading the diagnostic imaging and therapeutical approach, especially in complex malformations.

Nevertheless, for the analysis in this chapter of the clinical aspects of congenital uterine abnormalities, associated or not to mesonephric or extragenital anomalies, we will follow the classification based on the Müllerian development processes presented in [Table 1](#). In [Fig. 2](#) the uterine or Müllerian malformations are graphically exposed.

Previous Considerations

(1) We consider the arcuate uterus as a minor form of the bicornuate uterus, although in the AFS classification it is rather a kind of subseptate uterus and sometimes it can be so; in the ESHRE/ESGE classification it is not considered; (2) any depression in the

Table 2 Embryological-clinical classification for female genito-urinary malformations

-
1. Unilateral genito-urinary agenesis or hypoplasia. They are the cases of unicornuate uterus with contralateral renal agenesis due to agenesis or hypoplasia of an entire urogenital ridge.
 2. Uterine duplicity (bicornuate or didelphys uterus) with a blind hemivagina (or unilateral cervico-vaginal atresia) and ipsilateral renal agenesis. It includes the Herlyn–Werner and Wunderlich syndromes and there can also be cases of partial resorption of the intervaginal septum.
 3. Isolated or common uterine or utero-vaginal anomalies. They include the anomalies in the Müllerian development processes also included in the classification of the [American Fertility Society \(1988\)](#) without other associated anomalies; and also the transverse vaginal septum.
 4. Accessory uterine masses (ACUMs) with an otherwise normal uterus, and other possible gubernaculum dysfunctions.
 5. Anomalies of the urogenital sinus. As imperforated hymen, vesico-vaginal fistulas, persistent urogenital sinus, cloacal anomalies, and other external gastrointestinal or urinary anomalies.
 6. Malformative combinations
-

Revised and updated from Acien, P. (1992); Acien, P., Acien, M. and Sánchez-Ferrer, M. (2004) and Acien, P. and Acien, M. (2011). The history of female genital tract malformation classifications and proposal of an updated system. *Human Reproduction Update* **17**, 693–705.

Fig. 2 Graphical representation of uterine or Müllerian malformations. (1) Rokitansky syndrome. (2) Cervico-vaginal agenesis. (3) Unicornuate uterus. (4) Didelphys uterus. (5) Bicornis-bicollis uterus. (6) Bicornis-unicollis uterus. (7) Septate uterus. (8) Subseptate uterus. (9) Arcuate uterus. (10) DES-related uterus. (11) T-shaped hypoplastic uterus. (12) ACUM.

uterine bottom, on its outer surface, makes the malformation then to be included as a bicornuate uterus and not septate, since in this case the external shape of the uterus is supposed to be normal and uniform (this is basically the problem when cataloguing uterine malformations in different publications); (3) many cases are transitional (fusion and reabsorption partial failure). The cataloguing of these cases is sometimes difficult because the upper part is bicornuate (fusion defect, practically didelphys) and is clearly septate (reabsorption defect) lower down. The ESHRE/ESGE classification includes these cases as bicorporal septate uterus. And the other way around, we can also find a septate-bicervical uterus (Acien et al., 2009); (4) the uterus is didelphic when there are two hemiuteri completely detached, at least up to the cervixes, where they may be touching each other. But, as already mentioned, there are also cases with double uterine body and isthmic portion, but with simple exocervix and vagina. They are anatomically and clinically didelphic uteri; (5) we agree with Muller and Musset's bidirectional theory (1967) on the reabsorption of the uterine septum, since when there are communicating uteri, they are generally communicating at an isthmic level and besides, this is always the weakest part of the septum. The explanation to this is in the different portions of the Müller ducts which give rise to different uterine portions and, specifically, to the convergence in the internal cervical os of the Müller ducts with distal divergence up to the external cervical os (Sánchez-Ferrer et al., 2006); (6) the septate or double vagina is associated to a didelphys and bicornis-bicollis uterus, but also to a septate uterus; and the vagina can be septate even in the presence of a normal uterus or of non-septate (Acien et al., 2009).

Clinical Presentation and Diagnosis

Agenesis

1. The combined uterovaginal agenesis is the most common type of agenesis (bilateral Müllerian agenesis) and it corresponds with the MRKH or Rokitansky Syndrome (Oppelt et al., 2012). This is an isolated Müllerian anomaly affecting both the Müllerian tubercle and ducts. Patients report primary amenorrhea. Transrectal ultrasound (TRU), computerized axial tomography (CT) or

the magnetic resonance (MR) demonstrate uterus absence with normal ovaries and two solid rudimentary horns. Some of these rudimentary horns may occasionally present a small functioning endometrial cavity, giving rise to retrograde menstruation, endometriosis and cyclical pain (Acíén and Acíén, 2016a). Occasionally, the cavitated rudimentary horn might be well developed, being possible its implantation in a previously formed neovagina (Grimbizis et al., 2015; Acíén and Acíén, 2016a).

In cases of agenesis or hypoplasia of a urogenital ridge, there will be absence of kidney, ureter, ovary, fallopian tube, hemiuterus, and hemivagina (not detectable) on one side. On the other side there might be a unicornuate uterus, but if there is also contralateral Müllerian agenesis, the diagnosis will be Rokitansky syndrome with unilateral renal agenesis (Acíén et al., 2010b) or atypical Rokitansky. This condition is sometimes associated with skeletal and/or auditory anomalies (Acíén and Acíén, 2010). Apart from the primary amenorrhea, the clinical presentation of the Rokitansky syndrome involves the difficulty for sexual intercourse and infertility, with normal sexual development, the absence of dysmenorrhea and the absence of a vagina under gynecologic examination. Laparoscopy generally reveals a fibrous tract or two solid rudimentary horns and normal ovaries with the distal portion of the tubes.

2. *Cervico-vaginal agenesis and segmentary atresias.* There might be isolated Müllerian anomalies affecting the Müllerian tubercle presenting as complete vaginal (or cervicovaginal) agenesis or atresia; and also segmentary atresias affecting one of the Müllerian ducts (see unicornuate uterus), or the Müllerian tubercle, as in cases of transverse vaginal septum.

Complete vaginal or cervicovaginal agenesis or atresia with a functional uterus is usually a complex malformation in which the external genitals and tubes appear normal. The uterus may be normal or may present with fusion or resorption defects and the cervix may be present, absent or hypoplastic. The clinical presentation involves primary amenorrhea and cyclic pain in post pubertal women. TRU and particularly MR allow a clear diagnosis that includes a normal corpus uteri with endometrium and cervicovaginal atresia. The ovaries are normal, although they might present endometriosis due to retrograde menstruation. Laparotomy with atretic cervix resection and implantation of the uterine corpus in a previously formed neovagina is recommended, having achieved normal menstruations and spontaneous term pregnancy (Acíén et al., 2008).

The vaginal segmentary atresia and transverse vaginal septum correspond to a transverse constriction or septum that is perforated or imperforated. There may be no symptoms until puberty, when the hematocolpos forms and causes episodes of pelvic pain and primary amenorrhea similar to those observed with vaginal atresia. The examination, abdominal or TRU and specially MR allow the diagnosis and help on the surgical evacuation of the hematocolpos. Uterus, fallopian tubes and ovaries are usually normal.

3. *Unicornuate uterus* comes in several variations, based on the degree of development and absence of communication to the contralateral side (see Fig. 3). It can be easily diagnosed with hysterosalpingography (HSG), but attention must be given for the possibility of a didelphys uterus with unilateral canalization and contrast injection. Nowadays, it is a better tool the 3D-US and MR of special interest in the detection of a cavitated non-communicated uterine horn which can also be observed with transvaginal ultrasound (TVU) (or with TRU). It must be remembered that in all isolated Müllerian anomalies both kidneys will be present, but some cases of unicornuate uterus might have a cavitated and non-communicating uterine horn with external bicornuate uterine morphology. The inclusion of these cases as bicornuate or unicornuate uterus is discussed. Functionally, these uteri are unicornuate, but it is important to adequately identify the anomaly to determine whether there is renal agenesis and to decide if surgical excision is required. Patients may experience dysmenorrhea and present endometriosis and ovarian endometriomas in the non-communicating horn side, but sometimes, there are no symptoms or adnexal pathology. Sometimes, the severe symptoms appear after bilateral tubal sterilization following several uneventful pregnancies. Tubal blockage of the side with the cavitated and non-communicating horn led to unilateral haematometra with severe dysmenorrhea. Other times, in the cavitated rudimentary horns (communicated or not), there can be gestation with a possible uterine rupture, usually at the end of the second trimester.

In cases of segmentary atresia of one of the Müllerian ducts with a detached hemiuterus, the HSG will be that of a unicornuate uterus but ultrasound and MR show a didelphys uterus in the superior uterine segment with a unilateral cavitated and non-communicating uterine horn. The cervix is simple. There will generally be dysmenorrhea and endometriosis due to retrograde menstruation from the cavitated uterine horn, but there can also be tubal segmentary atresia and in such cases there will be hematometra without endometriosis. In any case, a differential diagnosis must be determined, mainly with cases of complete unilateral vaginal or cervicovaginal agenesis without communicating uteri.

Fig. 3 Graphical representation of the unicornuate uterus subtypes. (1a) With non cavitated rudimentary horn. (1b) Unilateral Rokitansky. (2a and 2b). Cavitated and non-communicated uterine horn. (3) Segmentary atresia of one of the Müllerian ducts with a detached hemiuterus.

The reproductive results of the unicornuate uterus are worse than those in women with normal uterus (abortions: 20% vs. 8%; preterm deliveries: 20% vs. 4%; living children older than 7 days: 70% vs. 89%) but better than in other types of malformations (Acíén, 1993; Acíén et al., 2014). The probability of spontaneous miscarriage during first and second trimester was increased (RR 2.10, 95% CI 1.12–3.94), as well as low birth weight (<2500 g) incidence (RR 3.54, 95% CI 2.22–5.54) compared to controls, in Venetis et al. (2014) meta-analysis.

Fusion defects (didelphys and bicornuate uteri)

1. *Didelphys uterus* presents two completely detached hemiuteri (like two unicornuate uteri) with two cervixes and a double vagina. The new ESHRE/ESGE classification system (2013) has assimilated the didelphys to bicornuate uterus including it as a complete bicorporeal uterus (U3/C2/V2). For the diagnostic imaging, the considerations made on the resorption of the septum and the bidirectional hypothesis of Musset and Müller (Muller et al., 1967) have to be taken into account, and cases with didelphic uterine corpus and simple (normal or septate) cervix and vagina can be found. Apart from the fertility related problems (obstetric mainly), the only symptom might be dyspareunia due to the vaginal septum, but it usually does not present. The probability of pregnancy in natural cycles was not significant different from the controls (RR 0.94, 95% CI 0.83–1.07) (Venetis et al., 2014). And the reproductive results are similar to the unicornuate uterus in our material: 72% of living children (Acíén, 1993), or 91% if there is associated ipsilateral renal agenesis (Acíén et al., 2014); much better than the 40% published by Raga et al. (1997). The miscarriage risk during first and second trimester did not differ from controls but it did the birth weight and intrauterine growth restriction rate in Venetis et al. (2014) meta-analysis.

2. *Bicornuate uterus*: it corresponds to the complete (bicornis-bicollis uterus) and partial (bicornis-unicollis uterus) in the AFS/ASRM classification (1988) or partial, complete, and bicorporeal septate uterus in the new ESHRE/ESGE classification (2013). Some cases can have a cavitated non-communicating horn and their inclusion as bicornuate/septate or unicornuate uterus is discussed. Currently, sonohysterography, 3D-US, and specially the MR may provide the differential diagnosis with the septate uterus without the need of laparoscopy. In a pelvic MR, significant fundal cleft (> 1 cm) indicates no fusion of the upper-mid uterine horns (Graupera et al., 2015). However, if this distance measures < 1 cm, then a septate uterus would be present. In the ESHRE/ESGE classification system (2013), class U3 (bicorporeal uterus) is defined by an external indentation of > 50% of the uterine wall thickness, whereas in the complete bicorporeal uterus (U3b), the width of the fundal indentation at the midline is > 150% of the uterine wall thickness.

The reproductive results in the bicornuate uteri group are worse in cases of bicornis-unicollis uterus (40% of living children older than 7 days) than of bicornis-bicollis (71%) in our material (Acíén, 1993), and in latter analysis: 45% and 65% respectively (Acíén et al., 2014). Also the miscarriage rate is worse in the bicornuate-unicollis (45%) than in the bicornis-bicollis (23.5%). In the Venetis et al. (2014) meta-analysis, there were no statistically significant differences in the probability of pregnancy in natural cycles (RR 0.95) nor under assisted reproductive techniques cycles (RR 1.73) in the bicornuate uterus; but it was higher the first trimester miscarriage rate (RR 2.32), the second trimester (RR 2.90), premature delivery < 28 weeks (RR 5.37), malpresentation (RR 4.65), very low neonatal birth weight (RR 2.78), intrauterine growth restriction (RR 2.80) and perinatal mortality (RR 3.32, 95% CI 1.61–6.86).

3. The fusion Müllerian defects associated to distal mesonephric anomalies (unilateral renal agenesis and ipsilateral blind or atretic hemivagina syndrome) are the most complex malformations; they include uterine duplicity (didelphys, bicornuate or less commonly, septate uterus), renal agenesis (or dysplasia with or without ectopic ureter), and any of the following subtypes (see Fig. 4): (a) large hematocolpos in a blind hemivagina; (b) “Gartner’s duct pseudocyst” in the anterolateral wall of the permeable vagina; (c) partial reabsorption of the intervaginal septum; or (d) complete unilateral vaginal or cervicovaginal agenesis (Acíén and Acíén, 2016a). The last cases can have communication between both hemiuteri and will present as a bicornuate-unicollis uterus. In other cases, there is no communication between the hemiuteri and these cases reflect unilateral hematometra and endometriosis caused by retrograde menstruation on the side of the absent vagina and kidney. In the latter, differential diagnosis must be done with Müllerian segmentary atresias. 2D and 3D-US, pyelography, and MR can help in the diagnosis and treatment includes a hemi-hysterectomy. Reproductive performance was significantly better for a given type of uterine malformation if it was associated with unilateral renal agenesis (URA) (Acíén et al., 2014).

Resorption Defects (Septate, Subseptate) and Arcuate Uterus

1. *Septate uterus*. Corresponds to the complete (septate uterus) and partial (subseptate uterus) in the AFS/ASRM classification (1988) or complete (U2b) and partial (U2a) septate uterus in the new ESHRE/ESGE classification (2013). The diagnosis is equally suggested by TVU and 3D-US, or by HSG. Currently, sonohysterography, 3D-US, CT, and specially MR can provide the appropriate differential diagnosis (Graupera et al., 2015). Imaging description for septate uterus in the AFS/ASRM classification (class V) is convex, flat or minimally indented (< 1 cm) fundal external contour with indentation of the myometrium/septum into the uterine cavity (> 1 cm). In the ESHRE classification (2013), class U2 (septate uterus) is considered by an internal indentation > 50% of the uterine wall thickness and external contour straight or with indentation < 50%. The clinical presentation are reproductive losses, preterm deliveries, breech presentation and eventually hemi-hematometra if there is a non-communicating cavitated uterine horn (Robert’s uterus) (Acíén and Acíén, 2016a).

Fig. 4 Subtypes of unilateral renal agenesis and ipsilateral blind or atretic hemivagina syndrome: (1) with large hematocolpos in a blind hemivagina. (2) With “Gartner’s duct pseudocyst” in the anterolateral wall of the permeable vagina. (3) With partial reabsorption of the intervaginal septum. (4) With complete unilateral vaginal or cervicovaginal agenesis and no communication between hemiuteri. (5) Idem with communicating uteri.

The chances for achieving a pregnancy during natural cycles are significantly decreased in women with septated uterus compared with normal controls (RR 0.86, 95% CI 0.77–0.96), but there are no statistically significant differences in women undergoing assisted reproductive techniques cycles (Venetis et al., 2014). The reproductive results in our material (Acien et al., 2014) were similar between the septate and subseptate uterus but with a 40% of miscarriage rate and 55%–51% living children. In the Venetis et al. (2014) meta-analysis, women with septated uterus had a higher rate of first-trimester spontaneous abortion (RR 2.65, 95% CI 1.39–5.06), of second-trimester spontaneous abortion (RR 2.95, 95% CI 1.51–5.77), of malpresentation at delivery (RR 4.35, 95% CI 2.52–7.50), of growth restriction (RR 2.54, 95% CI 1.04–6.23), placental abruption (RR 4.37, 95% CI 1.12–17.08) and perinatal mortality (RR 2.43, 95% CI 1.10–5.36) compared to controls. After hysteroscopic resection of the septum, the probability of achievement of pregnancy was not significantly different (RR 1.14, 95% CI 0.79–1.65) nor the preterm delivery rate reduction (RR 0.66, 95% CI 0.29–1.49), but it did have a significant reduction the spontaneous (combined first-trimester and second-trimester) abortion rate (RR 0.37, 95%; CI 0.25–0.55).

2. *Arcuate uterus* is a minor form of bicornuate uterus, although in the AFS/ASRM classification (1988) it is rather a kind of subseptate uterus. It has not been included in the new ESHRE/ESGE classification system (2013).

The chances of achieving a pregnancy in natural cycles and under assisted reproductive techniques cycles has not been significantly different in women with arcuate uterus on Venetis et al. (2014) meta-analysis. However, it was significantly higher the spontaneous second trimester miscarriage risk (RR 1.98, 95% CI 1.06–3.69), placental abruption (RR 6.60, 95% CI 2.35–18.53) and malpresentation at delivery (RR 2.53, 95% CI 1.45–4.43).

Lack of Posterior Development (Hypoplastic Uterus, T-Shaped, and Diethylstilbestrol Exposure [DES] Syndrome)

Anomalies related to DES syndrome include hypoplastic, tricavitated, and T-shaped hypoplastic uteri with an extremely small uterine cavity, cornual constrictions, and bulbous dilatation of the lower segment. In the new ESHRE/ESGE classification (2013), these anomalies are included as dysmorphic uterus (class U1). From the clinical point of view, most cases are asymptomatic, though it can be associated with menstrual irregularities (hypo or oligomenorrhea), infertility and recurrent pregnancy losses or implantation failures in an IVF programme. Cervical ridges, folds or ectropion with a “glans” aspect, pseudopolyps or cervix hypoplasia may be observed. The diagnosis is made by HSG. Here, the ultrasound is less useful (though it may be suspected with it) and the laparoscopy usually shows normal internal genitalia. The hysteroscopic metroplasty may enhance the fertility and the reproductive performance.

Gubernaculum Dysfunctions

These cases are typified by accessory and cavitated uterine masses (ACUMs) with an otherwise normal uterus. HSG will show normal endometrial cavity and 3D-US and especially MR allow the right diagnosis. Although not properly being a uterine malformation that affects the endometrial cavity, it might provoke relevant symptoms due to menstrual retention in the ACUM. It represents a variant of Müllerian anomaly that is generally located at the level of the insertion of the round ligament and is possibly related to a dysfunction of the female gubernaculum (Acien and Acien, 2011; Acien et al., 2012). Other uterine malformations (e.g., didelphys uterus, Rokitansky syndrome) may also be due to gubernaculum dysfunctions (Acien et al., 2011) affecting the Müller duct development.

The criteria used to diagnose ACUM include the following: (i) an isolated accessory cavitated mass; (ii) a normal uterus (endometrial lumen), fallopian tubes, and ovaries; (iii) a surgical case with an excised mass and a pathological examination; (iv) an accessory cavity lined by endometrial epithelium with glands and stroma; (v) chocolate brown-colored fluid content; and (vi) no adenomyosis (if the uterus has been removed), although there could be small foci of adenomyosis in the myometrium adjacent to the accessory cavity (Acien et al., 2010a, 2012).

ONCOFERTILITY

Cervical Cancer

Melissa Schwartz and Linus Chuang, Icahn School of Medicine at Mount Sinai, New York, NY, United States

© 2018 Elsevier Inc. All rights reserved.

Glossary

Cervical transformation zone An anatomic area of the cervix that contains the transition from ectocervical squamous epithelium to endocervical glandular epithelium.

Colposcopy Procedure used to evaluate the cervix by magnification in order to identify abnormal cells and vascular changes.

Human papillomavirus (HPV) A double-stranded DNA virus with over 40 different types that can infect the genital area and can cause warts as well as cervical cancer. It is the most common sexually transmitted infection in the United States.

Papanicolaou (Pap) test A screening test for cervical cancer in which a smear of exfoliated cells from the cervix are examined under a microscope for abnormal cells.

Parametria Connective tissue that extends laterally from the supracervical portion of the uterus between the broad ligament.

Introduction

Cervical cancer is the third most common gynecologic cancer and cause of gynecologic cancer-related death in the United States ([Berek and Hacker, 2015](#)). The Papanicolaou (Pap) test from screening has decreased the incidence of and mortality from cervical cancer as preinvasive disease and early stage cervical cancers are now more readily detected. Human papillomavirus (HPV) is integral to the development of cervical cancer and is detected in 99.7% of cases. There are two major histologic types of cervical cancer, squamous cell carcinoma and adenocarcinoma, and each has associated precursor lesions. In advanced stages, cervical cancer is a terminal disease.

Epidemiology

Globally, there were over 528,000 new cases and 266,000 deaths due to cervical cancer in 2012. On the other hand, in the United States, cervical cancer is relatively uncommon with approximately 13,000 new cases and 4100 deaths are due to cervical cancer annually ([Berek and Hacker, 2015](#)). These disparate statistics are due to a lack of access to screening and HPV vaccination in developing countries.

The lifetime risk of developing cervical cancer in the United States is estimated to be 0.6%. Cervical cancer incidence and mortality are higher among non-Hispanic black and Hispanic women as opposed to white and Asian women. The mean age of diagnosis 48 years, with very few women diagnosed after age 85 years.

Risk Factors

It has been well-established that persistent infection with HPV is the main cause of cervical cancer ([Cannistra and Niloff, 1996](#); [Schiffman et al., 2007](#)). Two high-risk HPV types, 16 and 18, are responsible for approximately 70% of cervical cancer ([Schiffman et al., 2007](#)). HPV infection is extremely prevalent with a lifetime risk of 80%. However, most of these infections clear spontaneously in immunocompetent individuals within 6–12 months. Risk factors for cervical cancer are predominantly associated with either acquiring the HPV infection or not having the appropriate immune response to fight off HPV infection.

HPV is known to be a sexually transmitted infection. Therefore, cervical cancer has been associated with early onset of sexual activity, increased number of lifetime sexual partners, and having a high-risk sexual partner ([Cannistra and Niloff, 1996](#); [Schiffman et al., 2007](#)). A high-risk partner is someone who has had multiple sexual partners or a known HPV infection. A history of sexually transmitted infections is also a risk factor for cervical cancer. Increasing parity (≥ 3 full term births) and early age at first birth (< 20 years) are also associated with increased risk of cervical cancer.

Human immunodeficiency virus (HIV) causes immunosuppression and a compromised immune response to HPV resulting in persistent infection and increased risk for cervical precancerous lesions to transform into cancer ([Cannistra and Niloff, 1996](#)). Cigarette smoking increases the risk for squamous cell cancer of the cervix, but not adenocarcinoma. Lastly, non-white race and low socioeconomic status have been associated with increased risk of cervical cancer.

Pathogenesis

Cervical cancer is an HPV-associated malignancy. Although genital tract infection with HPV is common, only a small percentage of women develop cervical cancer. Approximately 15 types of HPV have been identified as oncogenic with HPV 16 and 18 being the most common (Schiffman et al., 2007). Most HPV infections are transient and infection with HPV alone does not cause cervical cancer. In order for cervical cancer to develop, an oncogenic HPV strain must first infect the metaplastic epithelium of at the cervical transformation zone. Persistent HPV infection then permits tumorigenesis. If HPV is not cleared, infected epithelial cells can then transform and invade through the basement membrane to become invasive carcinoma. Cervical cancer spreads by direct extension or lymphatic or hematogenous dissemination.

Signs and Symptoms

The most common presenting symptom for patients with cervical cancer is painless vaginal bleeding. This bleeding can be postcoital or postmenopausal. Rarely, patients present with life-threatening hemorrhage requiring immediate intervention. For some women, the presenting symptom is vaginal discharge that can be malodorous or watery. In advanced stages of disease, women may complain of lower back pain, unilateral leg pain or leg edema. These symptoms may indicate that the tumor has invaded the pelvic sidewall. Patients may also have urinary symptoms or recurrent urinary tract infections caused by tumor compression of the bladder or ureters. For many women, especially those with early stage disease, there may be no presenting symptoms, with the diagnosis of cervical cancer made during screening with the use of a Pap test or incidentally during routine pelvic examination.

Diagnosis

Cervical cancer diagnosis is based on histologic evaluation of a cervical biopsy. Any women with symptoms suggestive of cervical cancer should undergo a complete pelvic examination. A speculum examination should also be performed to allow for visualization of the cervix. Any grossly visible cervical lesion should be biopsied. Symptomatic women without a visible cervical lesion should undergo colposcopy and directed biopsy. An adequate colposcopy requires that the entire squamocolumnar junction and any lesions be completely visualized (Cannistra and Niloff, 1996).

Bimanual examination should be performed for palpation and estimation of size of cervical tumor size. The uterus and adnexa should also be assessed. The size and shape of the uterus as well as any adnexal masses should be noted and characterized. A rectovaginal exam should also be done in order to better assess for vaginal, parametrial and pelvic sidewall involvement. The rectum should be palpated for any masses or extension of tumor. Other physical exam findings that are important include palpable groin or supraclavicular lymph nodes.

If a cervical biopsy shows cancer, certain tests can be ordered to assess for spread of disease. Oftentimes these additional tests are only done for large tumors. Additional tests include cystoscopy and proctoscopy. Cystoscopy entails inserted a lens and light through the urethra and into the bladder to assess for cancer in these areas. Proctoscopy allows for visual inspection of the rectum to assess for cancer spread to this area.

Cervical cancer is a clinically staged disease as opposed to surgical staging which is used for other gynecologic malignancies. The International Federation of Gynecology and Obstetrics (FIGO) (Mutch, 2009) utilizes clinical staging, which is largely based on physical examination, given that the majority of women with cervical cancer live in low-resource countries (Table 1). Surgical

Table 1 2009 FIGO staging for cervical cancer

Stage	Description
0	Carcinoma in situ (preinvasive)
I	Invasive carcinoma confined to the cervix
IA1	Stromal invasion ≤ 3.0 mm in depth and ≤ 7.0 mm in horizontal spread
IA2	Stromal invasion > 3.0 mm and ≤ 5.0 mm in depth and ≤ 7.0 mm in horizontal spread
IB1	Clinically visible lesion ≤ 4.0 cm in greatest dimension
IB2	Clinically visible lesion > 4.0 cm in greatest dimension
II	Invasive carcinoma that invades beyond cervix but not to pelvic sidewall or lower 1/3 of vagina
IIA1	Tumor without parametrial involvement. Clinically visible lesion ≤ 4.0 cm in greatest dimension
IIA2	Tumor without parametrial involvement. Clinically visible lesion > 4.0 cm in greatest dimension
IIB	Tumor with parametrial involvement
IIIA	Tumor extends to lower 1/3 of vagina, no extension to pelvic sidewall
IIIB	Tumor extends to pelvic sidewall and/or causes hydronephrosis or nonfunctional kidney
IVA	Tumor invades mucosa of bladder or rectum
IVB	Tumor extends beyond true pelvis

Mutch, D.G. (2009). The new FIGO staging system for cancers of the vulva, cervix, endometrium and sarcomas. *Gynecologic Oncology* 115, 325–328.

staging and advanced imaging modalities may not be available or feasible worldwide. Furthermore, locally advanced disease (i.e., tumor size, vaginal involvement, parametrial involvement) may be better assessed clinically and avoids surgery in women who are not candidates for surgical treatment. Staging procedures include a complete physical exam, cervical biopsy, cystoscopy and proctoscopy, and intravenous pyelogram (IVP) and plain chest radiograph. An IVP is used to evaluate for urinary tract obstruction. A chest X-ray may be done to assess for cancer spread to the lungs.

In resource-rich countries, such as the United States, imaging studies may be performed in order to augment clinical findings and remains controversial. A computed tomography (CT) scan may be done to look for lymphatic spread and in many centers replaces IVP for assessment of urinary tract obstruction. A magnetic resonance imaging (MRI) study may be performed to look for soft tissue involvement. Lastly, a positron emission tomography (PET) scan, which is a nuclear medicine functional imaging technique, may be done to look for increased metabolic activity of rapidly growing tumors in the body.

Management

The management of cervical cancer is dependent on the stage of disease ([Cannistra and Niloff, 1996](#)). Treatment may involve surgery, radiotherapy, chemotherapy, or a combination of therapies. In the United States, 70% of patients with invasive cervical cancer are diagnosed at a stage limited to the cervix, and therefore potential operative candidates. As cervical cancer generally spreads by direct extension, the extent of surgery for localized disease becomes more radical.

Stage IA1 cervical cancer is usually treated with a simple hysterectomy ([Cannistra and Niloff, 1996](#)). Alternatively, if fertility-sparing treatment is desired, then a cold knife cone can be performed. However, if lymphovascular invasion is identified, then a radical hysterectomy should be considered ([Berek and Hacker, 2015](#)). Removal of the ovaries is not necessary as cervical cancer very rarely metastasizes to the ovaries. Stages IA2, IB1, and IIA1 disease can be treated with either radical hysterectomy and pelvic lymph node dissection or primary radiotherapy with concurrent chemotherapy ([Cannistra and Niloff, 1996](#)). Cure rates for radical surgery or radiotherapy with chemotherapy are similar. For stages IB2, and IIA2–IVA, the standard of care is to treat with combination radiotherapy with chemotherapy. Lastly, patients with IVB should be treated with chemotherapy for disseminated disease. In certain advanced stage cases, palliative radiation can be considered.

A number of patients treated surgically will need adjuvant treatment for intermediate or high-risk features ([Berek and Hacker, 2015](#)). The National Cancer Institute supports treatment with the fewest number of interventions. Therefore, if there is a high probability that adjuvant therapy will be needed after surgery, then surgery should not be performed. Intermediate risk features include presence of lymphovascular space invasion (LVSI), deep cervical stromal invasion, and large tumor size. In cases with intermediate-risk disease, adjuvant radiation should be given to decrease risk of recurrence. Women are considered high risk disease if any of the following features are present: positive surgical margins, positive pelvic lymph nodes, or microscopic involvement of the parametrium. Adjuvant treatment for high-risk disease is a chemoradiation.

Chemotherapy has a limited role in the treatment of cervical cancer as most patients are treated with surgery or radiation and have a good response. When chemotherapy is used it is generally given concurrently with radiation. The most commonly used agent is cisplatin as a radiosensitizer. Rarely is chemotherapy used for first-line treatment. The one exception is in cases of metastatic cervical cancer in which combination chemotherapy plus bevacizumab, an angiogenesis inhibitor, is the choice of treatment.

Recurrent disease is managed based on location of recurrence ([Cannistra and Niloff, 1996](#)). If recurrence is local, treatment can be directed, such as surgical resection or radiotherapy. For distant recurrence, chemotherapy can be offered. The role of neoadjuvant chemotherapy for cervical cancer continues to be explored. This mode of treatment has particular implications in low-income countries in which the majority of patients lack access to radiotherapy and present with advanced disease.

Survival

Mortality from cervical cancer is dependent on stage. Five years after diagnosis, survival is very good for early stage disease, but is dismal for advanced disease ([Berek and Hacker, 2015](#)). For treated stage IA (microscopic) disease, nearly 100% of patients are alive after 5 years. Conversely, survival rates for stage IV disease over the same time period range from 5% to 20%. In the United States, the overall survival rate of all patients diagnosed with cervical cancer is approximately 70%. This statistic is largely due to the fact that most cervical cancers in the United States are diagnosed early. Early diagnoses and prevention of cervical cancer is attributed to the Pap test and the HPV vaccine.

Prevention

Routine screening with the Pap test, also known as the Pap smear, was first adopted in the United States in the 1950s. Since the 1970s, the incidence and mortality from cervical cancer has decreased. The Pap test is a cytology-based test and is performed during a speculum exam ([Schiffman and Solomon, 2013](#)). Cells are collected from the cervix using a plastic spatula or soft brush and smeared on a slide for examination under a microscope. The cells are scrutinized for abnormalities. The Pap test is 65% sensitive

and 90% specific for detected abnormal cervical cells. As we have learned more about what causes cervical cancer, molecular testing for HPV has now become a part of screening. HPV testing is >90% sensitive and >90% specific for cervical dysplasia.

The optimal screening method (Pap test, HPV testing, or both) and continues to be debated. The frequency of screening also remains controversial. Current national guidelines recommend that cervical cancer screening be initiated at age 21 years and continued until 65 (Berek and Hacker, 2015). Screening should occur every 3–5 years. It should be noted that positive screening tests generally need to be followed up with a diagnostic test or repeat screening testing needs to be performed at a shorter screening interval. Confirmatory diagnostic testing typically entails a colposcopy with directed cervical biopsies for histopathologic diagnosis.

Another component to prevention of cervical cancer is HPV vaccination. Being vaccinated for HPV reduces the risk of cervical precancers and cancers by >92% by protecting against HPV 16 and 18. HPV vaccination is recommended as a part of routine vaccinations between the ages of 9 and 26 years old.

Glossary

Colposcope Medical instrument to examine cervix and vagina under magnification.

Dystrophy Abnormal growth of skin on the vulva.

Eczematoid Eczema like skin condition.

Histology Microscopic tissue study.

Immunodeficiency Deficiency in immune response.

Infiltrative Penetrating into the deeper tissues.

Intraepithelial Remaining within the skin.

Lymphadenectomy Removal of lymph nodes.

Lymphedema Persistent tissue swelling from lymphatic fluid after removal of lymph nodes.

Lymphocyst Collection of lymph fluid after removal of lymph nodes.

Malignancy Cancerous growth.

Neoplasia New uncontrolled growth of cells.

Premalignant Precancerous stage.

Introduction

Vulvar cancer is a rare condition, accounting for approximately 5% of all gynecological cancers and < 1% of all cancers diagnosed in women. Typically, vulvar cancer has been considered a disease of old age but increasingly is being diagnosed in younger women. Although arising from an external site, vulvar cancer is often diagnosed at a late stage due to delay in seeking medical advice and delayed diagnosis.

Histologically, squamous cell carcinomas account for the vast majority (85%–90%) of vulvar cancers, with melanomas, basal cell carcinomas, Bartholin's gland carcinomas, invasive Paget' disease and adenocarcinomas arising from the skin appendages accounting for the rest.

The last century has witnessed vast improvements in the management of vulvar cancer, with a significant improvement in 5-year survival. Improved surgical techniques have also improved overall quality of life following treatment ([Hacker and Eifel, 2015](#)).

Risk Factors for Squamous Cell Carcinoma

The risk factors for developing squamous cell vulvar cancer include:

- Smoking
- Vulvar dystrophies such as lichen sclerosus
- Human papilloma virus (HPV) infection
- Vulvar intraepithelial neoplasia (VIN), a premalignant condition of the vulvar skin
- Immunodeficiency syndromes and immunodeficiency states such as post organ transplantation
- Prior history of cervical cancer, which reflects the common association with HPV infection

Vulvar intraepithelial neoplasia (VIN) is an important precursor lesion for vulvar cancer. The International Society for the Study of Vulvovaginal Disease (ISSVD) classifies VIN into two types: the "usual type VIN," which is related to HPV infection and the "differentiated VIN" which is unrelated to HPV and is often diagnosed in association with the diagnosis of lichen sclerosus ([Sideri et al., 2004](#)).

Similarly, two etiologic types of vulvar cancer are recognized. The first type, often diagnosed in younger women, is related to HPV infection and smoking, and is commonly associated with usual type VIN. The second type is diagnosed more commonly in elderly women, is often associated with vulvar dystrophy, most commonly lichen sclerosus, is sometimes associated with differentiated VIN, and is unrelated to HPV infection.

Histologic Types of Vulvar Cancer

Squamous cell carcinoma (SCC) is, by far, the predominant histologic type comprising over 90% of all vulvar cancers. This chapter will concentrate on the management of squamous cell carcinomas.

Melanoma is the second most common type of vulvar cancer, and represents about 5%–10% of lesions. They occur predominantly in post-menopausal white women, most frequently on the labia minora and clitoris (**Fig. 1**). There are no well-defined risk factors that may predispose to the development of vulvar melanomas. Most melanomas are asymptomatic, and any pigmented lesion on the vulva should be biopsied, unless it is known to have been present and unchanged for a long time.

Basal cell carcinomas (BCC) comprise approximately 2% of all vulvar malignancies. Like BCCs elsewhere in the body, they progress locally, but rarely spread to lymph nodes.

Extramammary Paget's disease accounts for <1% of vulvar malignancies. It mainly presents as intraepithelial malignancy, but about 20% are associated with an underlying adenocarcinoma. It predominantly affects post-menopausal white women, and usually presents with vulvar itching and soreness. Clinically, the lesion has an eczematoid appearance, and usually begins on the hair-bearing areas of the vulva. Occasionally, the vulvar disease is secondary to a cancer of the bowel or cancer arising in the bladder, particularly if it is located around the anus or urethra. Even after wide surgical excision, the intraepithelial Paget's disease frequently recurs, because microscopic disease usually extends well beyond the macroscopic lesion (**Fig. 2**).

Bartholin's gland cancer is the least common of the epithelial cancers arising in the vulva. They are usually adenocarcinomas, but may be squamous cell carcinomas if the tumor arises from the duct. These tumors are solid and deeply infiltrative and often diagnosed late due to being misinterpreted as a Bartholin's gland abscess. Not uncommonly, a woman presents with what is thought to be a recurrent Bartholin's gland abscess, but this should raise a suspicion of an underlying malignancy. Bartholin's gland abscess is rare in a postmenopausal woman and should always be regarded as suspicious for malignancy.

Sarcomas, most commonly leiomyosarcomas, are connective tissue tumors that are known to arise as primary tumors in the vulva on rare occasions.

Fig. 1 Melanoma of left labium majus.

Fig. 2 Paget's disease of the vulva.

Clinical Presentation

The signs and symptoms of all histologic types are similar. Most women present with a vulvar lesion, ulcer or a mass. In 5% of cases, the origin of the disease is multifocal.

Vulvar itching and irritation, usually due to VIN or lichen sclerosis, have often been present for an extended period leading up to the diagnosis. Vulvar bleeding, discharge, painful urination, or lump in the groin are late symptoms, and often herald advanced stage disease at presentation. Symptoms of vulvar cancer can often mimic other benign conditions of the skin such as genital herpes, dermatoses, lichen sclerosis, fungal infections and benign genital warts (condyloma acuminatum).

Most cases of vulvar cancer develop on the labia majora. However, the disease can start in any part of the vulva including the clitoris, posterior fourchette and labia minora.

Diagnosis and Investigation

The initial assessment of vulvar cancer includes a thorough history of the presenting symptoms, their duration, an assessment of risk factors and physical examination. Diagnosis depends on biopsy of the lesion and histological review.

Physical examination may reveal an obvious mass or lesion that should be biopsied under a local anesthesia in most cases, but may require an examination under anesthesia if the area is too painful to allow biopsy in the clinic. In the case of small lesions or multifocal disease, application of acetic acid and examination using a colposcope may assist in mapping the extent of disease. More than one biopsy may be required if multifocal disease is suspected. Colposcopy should also be performed on the cervix and vagina, to exclude other foci of in situ or invasive squamous cell carcinoma, as many of these lesions are caused by the human papilloma virus.

The assessment of the vulvar tumor involves assessment of its fixity to underlying structures and its relationship to the midline. Tumors lying within 1–2 cm of the midline are more likely to involve lymph nodes bilaterally due to cross drainage of the lymphatics. The physical examination should include an assessment of any involvement of the vagina, anus or urethra, and the inguino-femoral lymph nodes should be palpated to rule out clinical involvement.

A workup to rule out metastatic disease is recommended even in the absence of obviously involved inguino-femoral lymph nodes. A chest X-ray and a CT scan of the pelvis and abdomen are reasonable for patients with early vulvar cancer. For patients with advanced disease, a positron emission tomography (PET) scan may be used to establish the extent of any metastatic disease. Pelvic lymph node involvement and or distant metastatic disease in other organs may have an impact on treatment decisions. Fine needle aspiration cytology (FNAC) may be performed on sites of apparent metastatic disease to confirm the diagnosis prior to definitive management.

Routes of Spread

Vulvar cancer spreads by

- Direct extension to involve adjoining structures such as the vagina, urethra and anus.
- Lymphatic spread to the lymph nodes of the groin or inguino-femoral nodes. The disease can spread to pelvic lymph nodes in up to 20% of patients who are diagnosed with metastatic disease in inguino-femoral lymph nodes. Involvement of lymph nodes can occur early and the risk increases as the size of the primary tumor and the depth of invasion increases—ranging from 7% for cancers measuring up to 1 cm in diameter to over 30% for cancers measuring over 3 cm ([Gonzalez Bosquet et al., 2007](#)). Overall, about 30% of women presenting with vulvar cancer will be diagnosed with lymph node involvement ([Hacker and Eifel, 2015](#)).
- Hematogenous spread via blood stream to distant sites such as the liver, and lungs. This is rare and a late phenomenon, usually noted only in women with involvement of multiple lymph nodes.

Staging

International Federation of Gynecology and Obstetrics (FIGO) adopted a surgical staging system for vulvar cancer in 1988, which was modified in 2009 ([Table 1](#)).

Principles of Treatment

Treatment of vulvar cancer involves treatment of the primary lesion and an assessment of the risk of involvement of the inguino-femoral lymph nodes. Wherever possible, primary surgery is the preferred modality of treatment, allowing for surgical staging and tailoring of adjuvant therapy if necessary.

Vulvar cancer was typically diagnosed at an advanced stage in the early part of the 20th century, and coupled with poorly developed surgical techniques; the survival rates were in the range of 20%–25%. Patients were treated by resection of the primary lesion

Table 1 FIGO surgical staging for vulvar cancer 2009

FIGO stage	Clinical/pathologic findings
Stage I	Tumor confined to vulva, no evidence of nodal disease
IA	Lesions measuring < 2 cm in size and < 1 mm deep
IB	Lesions measuring > 2 cm in size OR > 1 mm deep
Stage II	Tumor of any size with extension to adjacent perineal structures (lower 1/3 urethra, lower 1/3 vagina, anus) with negative nodes
Stage III	Tumor of any size with or without extension to adjacent perineal structures with positive inguino-femoral lymph nodes
IIIA	(i) 1–2 lymph nodes with metastases ≤ 5 mm
	(ii) 1 lymph node with metastasis ≥ 5 mm
IIIB	(i) ≥ 3 lymph nodes with metastases ≤ 5 mm
	(ii) ≥ 2 lymph nodes with metastases ≥ 5 mm
IIIC	Positive nodes with extra-capsular spread
Stage IV	Tumor invades upper two-third of regional structures like urethra and vagina OR distant metastases
IVA	(i) Tumor invades upper two-third of regional structures like urethra and vagina
	(ii) Fixed or ulcerated inguino-femoral lymph nodes
IVB	Any distant metastases including pelvic lymph nodes

Adapted from FIGO Committee on Gynecologic Oncology (2009). Revised FIGO staging for carcinoma of the vulva, cervix and endometrium. *International Journal of Gynecology and Obstetrics* **105**, 103–104.

without adequate resection of the groin and pelvic lymph nodes (Hacker and Eifel, 2015). Taussig in United States and Way from Great Britain pioneered radical surgery that dramatically improved the survival rates by threefold to 60%–70% (Taussig, 1940; Way, 1960). Their radical surgery for vulvar cancer involved radical vulvectomy with an en-bloc removal of the inguino-femoral lymph nodes (Fig. 3). Although vastly improving cure rates, the procedure was associated with severe post-operative morbidity including groin wound breakdown and infection, deep venous thrombosis and prolonged hospitalization. This procedure was often combined with pelvic exenterative procedures to remove disease involving the anus and the urethra.

There has been a paradigm shift in the management of vulvar cancer since the 1980s. These changes have consisted mainly of a more conservative resection of the primary tumor (radical local excision rather than radical vulvectomy), the use of separate incisions rather than an en bloc approach for the groin dissection, the use of unilateral rather than bilateral groin dissection for tumors which are not within 1–2 cm of the midline, and the appropriate integration of radiation therapy into the treatment protocol (Fig. 4). These modifications have been shown to significantly decrease post-operative without compromising survival (Hacker and Eifel, 2015; Taussig, 1940).

Anatomically, a radical vulvectomy involves the removal of the entire vulva, along with the subcutaneous tissues down to the periosteum of the pubic bone anteriorly and the deep urogenital fascia on the posterior and lateral aspects of the vulva. Radical vulvectomy is still occasionally required for very large lesions or for multifocal disease. It is associated with a high incidence of altered sexual function, body image issues and long-term psychological morbidity (Fig. 5A and B) (Andersen and Hacker, 1983).

Modified radical vulvectomy or radical local excision is now performed for unifocal lesions, with the intention of preserving the appearance and function of the vulva. This approach also allows for preservation of the clitoris in women diagnosed with posterior or lateral lesions. Removal of clitoris, whilst frequently unavoidable in anterior vulvar cancer, carries a particularly significant psychosexual morbidity.

**Fig. 3** En-bloc radical vulvectomy and bilateral inguino-femoral lymphadenectomy for a large squamous cell carcinoma of the vulva.

Fig. 4 Radical local excision and unilateral groin dissection for a left posterior vulvar cancer >1 cm from the midline.

Fig. 5 (A) Large vulvar cancer. (B) Radical vulvectomy and bilateral inguino-femoral lymphadenectomy through separate groin incisions for multifocal squamous cell carcinoma.

Our experience at the Royal Hospital for Women in Sydney would suggest that modified radical vulvectomy can be performed in over 90% of women with disease confined to the vulva, with an overall survival of about 95% at 5 years if the lymph nodes are negative for metastatic disease. The main reasons for performing radical vulvectomy were evidence of multifocal disease or widespread preinvasive disease in addition to the primary cancer ([Tantipalakorn et al., 2009](#)).

Regardless of whether a radical or modified radical vulvectomy is required, a margin of 1–2 cm of normal skin around the visible disease is necessary to avoid local recurrence. Because tissue contracts by about 20% once it is fixed in formalin, a macroscopic surgical margin of 10 mm equates to a histologic margin of 8 mm. If the histologic margin is <5 mm, further surgical resection is indicated. If this is not feasible, because of proximity to the anus or clitoris, for example, adjuvant radiation may be given.

Except in very early stage vulvar cancer (stage IA), patients need to undergo removal of the lymph nodes from one or both groins. Adjuvant radiation to the groins and pelvis may be required, depending on the status of the nodes.

Occasionally, the sequence of treatment may be reversed if there is a large cancer, which would necessitate radical vulvectomy combined with some type of exenterative procedure in order to resect the disease surgically. Primary radiotherapy may be used to shrink the tumor and hopefully avoid the need for urinary or bowel diversion.

Treatment of Early Stage Disease

Early stage vulvar cancer may be defined as (i) the primary tumor confined to the vulva or involving the distal urethra and/or vagina, and amenable to surgical resection without the need for exenterative surgery, and (ii) no clinically involved inguino-femoral lymph nodes.

Malignant vulvar lesions < 2 cm

For vulvar cancers where the maximal dimension of the lesion is < 2 cm and the preoperative biopsy shows a depth of invasion < 1 mm, radical local excision with surgical margins of at least 1 cm should be performed. The entire cancer should then be serially sectioned and examined histologically. If no foci with invasion deeper than 1 mm are found, no groin dissection is required. At least a unilateral inguino-femoral lymph node dissection is required if the final pathology shows the depth of invasion to be > 1 mm.

For tumors < 2 cm in maximal dimension, the risk of lymph node involvement increases with increasing depth of invasion. The risk is < 1% with invasion < 1 mm, increasing to approximately 34% with depth of invasion > 5 mm ([Hacker and Eifel, 2015](#)).

Performing the surgery in two stages with apparent stage IA disease spares a significant proportion of women from the risks and morbidity associated with inguino-femoral lymph node dissection.

Malignant vulvar lesions > 2 cm with or without involvement of adjacent structures

Women presenting with apparent stage IB and II disease (with involvement of the lower vagina or urethra) should be offered radical local excision, or radical vulvectomy if there is multifocal disease. Disease involving the distal urethra can be managed surgically, because at least 1 cm of terminal urethra can be resected without causing urinary incontinence.

Inguino-femoral lymph node dissection should be performed at the time of primary surgery. It is critical to appropriately manage the regional lymph nodes once the diagnosis of vulvar cancer has been confirmed, because recurrent disease in an undissected groin is associated with a very high mortality rate.

Unilateral groin dissection is appropriate for most tumors, but bilateral dissection is required for tumors that involve midline structures or encroach to within 1–2 cm of the midline.

Inguino-femoral lymph node dissection involves an incision just above and parallel to the groin crease. The major vessels of the lower limb, namely the femoral artery, femoral vein and the great saphenous vein, must be identified. The inguinal lymph nodes are situated in the femoral triangle between the superficial fascia and the fascia lata. The femoral nodes, usually only 1–3 in number, are located medial to the femoral vein under the cribriform fascia.

Treatment of Positive Inguinal-femoral Lymph Nodes

If one microscopic lymph node metastasis is found at inguino-femoral lymphadenectomy, no further treatment is required and the patient should have a very good prognosis. If two or more positive nodes are found, or if there is any extracapsular spread histologically, the patient should receive adjuvant groin and pelvic radiation. Earlier practice was to perform a pelvic lymphadenectomy when positive groin nodes were present, but a randomized trial conducted by the Gynecologic Oncology Group showed that these patients had better survival and fewer groin recurrences if treated with bilateral groin and pelvic radiation ([Homesley et al., 1986](#)).

Treatment of Advanced Vulvar Cancer

Advanced vulvar cancer includes disease that is associated with (i) extension of the cancer to the anus, or more proximal vagina and/or urethra, and/or (ii) clinically enlarged groin lymph nodes.

Treatment of Locally Advanced Vulvar Cancer

Vulvar cancer continues to be diagnosed in an advanced stage in a significant proportion of cases. The symptoms, such as itching, have usually been ignored for a prolonged period of time by the patient, and often treated with creams without physical examination by the physician.

Primary surgical management of advanced vulvar cancer would require radical vulvectomy and en bloc resection of one or more pelvic organs, such as the urethra and bladder, vagina and/or anus and rectum. A surgical approach would inevitably necessitate diversion of urine via an ileal conduit and/or fecal diversion via an end colostomy.

In recent years, primary treatment with radiotherapy has been used with great success to shrink or completely treat the vulvar cancer, and avoid the need for a stoma. The radiotherapy may completely eliminate the primary tumor in some cases, but in the majority of cases, it shrinks the tumor and allows a more limited vulvar resection, thereby preserving normal bowel and bladder function ([Moore et al., 2012](#)).

Primary radiotherapy leads to devascularization of the tissues, leading to poor wound healing. Hence, if a large vulvar resection is required as part of the primary treatment or for a local recurrence, there is often a need for plastic surgery. A myocutaneous graft is usually required from the abdomen, buttocks or thigh to close the resultant defect, and to bring a new blood supply into the area to aid in the healing process.

Treatment of Clinically Enlarged Groin Nodes

If patients present with palpably enlarged groin nodes, it is desirable to resect the enlarged nodes and obtain a frozen section to confirm that they contain metastatic disease. If the nodal enlargement is shown to be due to inflammatory changes only, complete inguino-femoral lymphadenectomy should be performed.

Much more commonly, the frozen section will confirm the presence of metastatic disease. In such patients, complete inguino-femoral lymphadenectomy can be avoided, because post-operative radiation will be required to the groins and pelvis, and this will sterilize any microscopic disease that may be present in the un-dissected lymph nodes (**Fig. 6**). Avoiding complete groin dissection in this circumstance minimizes the immediate post-operative risk of developing a lymphocyst or wound infection, so radiation can begin without any significant delay. It also decreases the risk of the later development of lower limb lymphedema ([Hyde et al., 2007](#)).

Rarely, a patient presents with groin nodes that are fixed to underlying structures, such as muscles or blood vessels, or even ulcerating through the skin. Radiotherapy, with or without chemotherapy, should be given, and if significant shrinkage occurs, it may be possible to resect the tumor mass. Erosion of a major femoral blood vessel and fatal hemorrhage is a rare complication.

Sentinel Lymph Node Detection

Sentinel node detection for vulvar cancer has been increasingly used over the past decade. The concept was initially introduced in 1977 for the management of men with penile cancer, and has subsequently been routinely adopted in the management of patients with breast cancer ([Cabanias, 1977](#)).

The hypothesis is that lymphatic drainage from a tumor occurs in an orderly fashion, and if the sentinel node (or nodes) is negative, all other nodes will be negative, so complete groin dissection can be avoided, thereby decreasing the risk of lower limb lymphedema.

The procedure involves the intraoperative intradermal injection of a tracer, isosulfan blue dye, around the tumor, preferably in conjunction with a radioactive colloid (technetium), which is injected several hours earlier. The blue dye tracer is visible to the naked eye, and a blue node can be identified in most cases (**Fig. 7**). The detection rate is increased by the use of the radiotracer, but a gamma probe is required intraoperatively to detect the radioactive node. If the sentinel node is histologically negative on routine hematoxylin and eosin staining, ultrastaging involves taking serial sections from the lymph node and performing immunoperoxidase staining for cytokeratin.

The main concern about sentinel node detection for vulvar cancer is the false negative rate, which will be at least 5%–10% in most centers. The reported false negative rates have ranged from 3% in the setting of the Groningen multicenter study in the Netherlands to 27% in a single center study from Poland ([Van der Zee et al., 2008](#); [Radziszewski et al., 2010](#)). Vulvar cancer is uncommon, and sentinel node detection is only appropriate for tumors up to 3–4 cm diameter, so individual experience with the technique will be limited. Recurrence in an un-dissected groin carries a high mortality and most patients, when properly informed, are not prepared to take this risk ([Farrell et al., 2014](#)). Hence, sentinel node dissection should only be performed for patients with vulvar cancer after properly informed consent.

Indications for Radiotherapy

Radiotherapy may be used for patients with vulvar cancer as primary treatment or in an adjuvant setting.

Fig. 6 Resection of a large positive lymph node from the left groin.

Fig. 7 Groin sentinel node detection using Patent Blue Dye.

Primary Radiotherapy

Radiotherapy may be offered as the primary treatment in patients where (i) the medical comorbidities preclude a surgical approach, (ii) there is locally advanced disease, and a surgical approach would necessitate a urinary stoma or colostomy, (iii) there are fixed and/or ulcerated inguino-femoral lymph nodes.

Occasionally particularly in younger patients, a small carcinoma involving the clitoris may be treated with radiation in order to preserve the clitoris.

Adjuvant Radiotherapy

Adjunct radiation is indicated in the following circumstances:

- To prevent local recurrence if the surgical margins around the primary tumor are close (<5 mm) or positive, and further resection cannot be undertaken (e.g., because of proximity to the anus or urethra).
- If more than one micro metastasis is identified after full inguino-femoral lymph node dissection. In this situation both groins and the pelvis should receive adjuvant radiation therapy.

Role of Plastic Surgery in Management of Vulvar Cancer

In most cases it is possible to achieve primary closure after surgical resection of a vulvar cancer. However, primary closure may not be possible if the cancer is extending onto the thigh or buttocks (**Fig. 8A–C**). Resection of recurrent cancers, particularly if there has been prior vulvar radiation, may also require some type of myocutaneous graft or pedicle flap, because radiation causes poor tissue vascularity and progressive fibrosis. It is important to have a plastic surgeon in the multidisciplinary team, because the disease is uncommon and the range of surgical procedures required is considerable.

Complications of Treatment for Vulvar Cancer

The major immediate post-operative morbidity relates to the groin dissection. Wound infection and breakdown have become much less common since the introduction of the separate incision approach, but lymphocyst formation occurs in about 40% of cases. Breakdown of the vulvar wound is relatively common, particularly for posterior incisions, the healing of which is hindered by sitting, but closure by secondary intention is always very effective ([Hacker and Eifel, 2015](#)).

Late complications include lower limb lymphedema from the groin dissection, which occurs in up to 60% of cases, and psychosexual distress from the vulvar surgery. It is important to provide ongoing support for both. As part of the multidisciplinary team management of vulvar cancer, early referral to a physiotherapist should be offered for lymphedema advice and management, and referral to a clinical psycho-oncologist should be offered for psychosexual counseling ([Hacker and Eifel, 2015](#)).

Fig. 8 (A) Large posterior vulvar cancer. (B) Radical local excision of a large posterior squamous cell carcinoma extending on to the right buttocks. (C) Large VY flap used to close the defect.

Conclusion

Vulvar cancer is best managed in the setting of a multidisciplinary team that includes a gynecological oncologist, radiation oncologist, clinical nurse specialist, clinical psychologist, a nursing team specializing in post-operative care following vulvar surgery, physiotherapist and a wound care practitioner. This is a very uncommon malignancy that requires life-long follow up because of its significant tendency to recur even many years later. In addition, the late side effects require ongoing care in a multidisciplinary team setting.

TREATMENT: SURGICAL

Current Techniques and Tools in the Surgical Treatment in Reproductive Medicine

Introduction

Selection

Surgery demands a strict selection of the patient and her pathology in order to be able to get acceptable results. If a comparative analysis is made between the requirements of in vitro fertilization and surgery the following can be analyzed:

1. *Age*: This factor is preponderant in both treatments. It can be discussed if a young patient, less than 30 years old, should be operated or not, but it would be unquestionably contraindicated for a 35 year old patient, because if the surgery treatment fails, after an 18 month wait her fertility will have decreased drastically due to age, and when she resorts to high complexity assisted fertilization techniques the results would be poor compared to the expectations of her initial age.
2. *Etiology of the illness*: This concept is fundamental in surgery; the recovery prognosis for tubal damage due to a compression adhesive process caused by endometriosis, where the endosalpinx is intact is not the same as the same obstruction caused by a bacterial endosalpingitis where the epithelium of the tube is severely affected. In the first instance the permeability is damaged, in the second the permeability and the functionality are damaged; this is of no concern for in vitro fertilization.
3. *Extent of the illness*: It's obvious that better surgical results are expected in minimal adherence processes, for example, delicate small, thin adherences without vascularization than in a total blockage of the pelvis due to firm, thick adherences with major vascular compromise; once again, this is indifferent for in vitro fertilization.
4. *Related sterility factors*: A profile of a low responsive female and/or an altered masculine factor, Assisted Reproductive Techniques are indicated; surgery is discarded.

Another determining factor in the use of surgery or high complexity techniques is the socio-economical environment.

Not acknowledging that in spite of living in a modern world, full of technology, the socio-economical situation of a patient or of a country can determine a therapeutical attitude is assistential blindness. In cases of personal or demographic poverty where there are no adequate means for the use of the latest technologies, surgery would be indicated even in those cases of poor prognosis.

Surgery can be approached in two ways: laparotomy, which implies going into the abdomen through a wound in the abdominal wall, or laparoscopy which employs endoscopy elements introduced in the abdomen through small incisions. The surgical technique to be used is microsurgery, which has nothing to do with the way that has been chosen.

Halfway through the 1960s microsurgery imposed fundamental concepts and principles which changed the surgical management of the female pelvis. It emphasize the need to treat the pelvic cavity and the related organs with a meticulous, purified surgical technique, with rigid guidelines, independently of the patient being sterile or not. If these recommendations are not followed, surgeons will be potentially responsible for causing severe damages that would make women sterile.

Simultaneously, the conservative factor in surgery was built up. A cycle of total ablations was over, to begin the era of surgeries where the motto was to keep the organs and not to stubbornly remove them surgically without a reason; only the ablation of the pathology should be performed. [Gomel \(1997\)](#) states: microsurgery got hold more than as a surgical technique as a "surgical philosophy."

Instrumental

This philosophical and tactical change in pelvic surgery drive to the manufacture of highly delicate instruments in order to be adequate for these new principles.

The use of magnification devices is essential in laparotomy: at least a magnifying glass; ideally, an operating microscope. This allows us to see with great augmentation structures that would be unseen with an unaided eye, minimal details of sections and super delicate sutures that would be impossible to observe with an unaided eye.

Small scissors, pliers, coagulators, similar to those employed in ophthalmology surgery, some of which have been adapted in length to pelvic surgery.

Irrigation and constant flush is mandatory, the drying of pelvic organs and blood clots are the main cause of post-surgery adhesences.

The use of non-absorbable sutures of extremely fine diameter, 3/0, 4/0, or 5/0, with atraumatic needles is an essential requirement for these procedures.

Table 1 Comparing delivery rate, ectopic pregnancy rate and CPR between laparotomy and laparoscopy surgery

		Laparotomy (59)	Laparoscopy (22)
Delivery rate (DR)		21(36%)	7(32%)
Ectopic pregnancy rate		3(5%)	2(9%)
CPR	12 months	36%	57%
	24 months	40%	57%

DR, delivery rate; CPR, cumulative pregnancy rate.

Laparoscopic surgery comes into the scene and its massive and definite consolidation at the end of the 1980s, although some articles were published between the end of the 1970s and beginning of the 1980s (Gomel, 1975; Mettler et al., 1979).

The difference between both methods is the way of getting into the abdomen, the magnification devices, and the type of surgical instruments employed; the rest of the principles of microsurgery are kept intact. Then, the election of the technique would rely on the criteria of each surgeon to evaluate which of the two techniques he feels more skilled with.

The present preference has, with absolute majority, steered towards the use of laparoscopy. Anyway, it should be pointed out that the percentage of pregnancies and the accumulative pregnancy index aren't different between both techniques.

This is stated in a publication by Saravelos et al. (1995) of the Sheffield group, where no difference is found between patients treated with both techniques (Table 1).

Around 10 years ago the laparoscopy increased its surgery methodology precision with the incorporation of robotics.

The robot allowed for a very peculiar control: the surgeon stays inside a computerized console and from there, through the use of joysticks, moves the surgical instruments with unsurpassable precision. Regretfully, the robot is terribly expensive and doesn't seem to pose any major advantages regarding reproductive purposes.

The hysteroscope together with the resectoscope are incorporated to the surgery reproductive therapeutic arsenal. Any damage that affect the uterine cavity are treated with them.

Surgical Techniques

The surgical techniques can be divided as follows:

1. Adhesiolysis or removal of adhesions.
2. Restitution of permeability of the Fallopian tubes.
3. Surgical removal of tumor-like pathologies.
4. Correction of malformations of the reproductive system.
5. With endocrinological purposes.

Adhesiolysis or Removal of Adhesions

Adhesiolysis or removal of adhesions is the surgical action that tends to free the genital-pelvic organs of the adhesions fixing them.

The proceedings which are used are: divulsion, that is, to detach, break and separate the adhered structures with dragging or separation blunt maneuvers with the tips of an instrument—a scissor or tweezers.

Section: The slack adherences are cut and, when possible, surgically removed with scissors, monopole electrodes or laser; the selection of the instruments employed doesn't seem to have any consequence regarding pregnancy and ectopic pregnancy.

When the adhesions are thick the direct cut with scissors is risky; it could involuntarily cause severe injuries in the compromised organs—bladder, bowel—with severe post-surgery consequences; it is in these instances where the experience and the skill of the surgeon prevail (Video 1 in the online version at <https://doi.org/10.1016/B978-0-12-801238-3.64753-0>).

The pregnancy percentage in adhesiolysis varies between 25% and 60%, with a 7% (Bruhat, 1983; Donnez, 1989; Favez, 1983; Gomel, 1983; Serour, 1989) ectopic pregnancy index (Table 2).

In the instance of uterine synechias, —adherences, which alters the uterus cavity—an operating hysteroscope, is employed, where a scissor or a mono or bipolar microelectrode is introduced through the operating channel to cut them. A resectoscope can be employed for this procedure, but its larger diameter is a drawback, implying the need to dilate the uterine cervix, which is not always an easy procedure.

Restitution of the Fallopian Tubes Permeability

The aim is to reestablish the integrity of the tubal lumen that for some reason has been totally or partially occluded.

The following are surgical techniques depending on which segment of the tube is affected:

Table 2 Pregnancy rate in adhesiolysis among different instrument used

<i>Author</i>	<i>Technique</i>	<i>No.</i>	<i>% Pregnancy</i>
Gomel (1983)	Scissors	92	62
Fayez (1983)	Scissors	50	56
Donnez (1989)	CO ₂ laser	186	58
Serour (1989)	Scissors-electrocoagulation	25	12
Bruhat (1983)	Scissors-electrocoagulation	93	52

Results in adhesiolysis.

Termino-terminal anastomosis

This technique is applied when the tubal lumen is obliterated at interstitial or medial level.

The goal is to join the two ends of the tube once the obstructed area has been removed.

When the obstruction is cornual (interstitial) the anastomosis can be performed between the isthmic portion of the tube and the uterine cornu. When it is medial, between the two healthy isthmic portion and among isthmic portion and the ampulla when obstruction is in the ampular-isthmic junction; therefore, there are three types of anastomosis: (a) isthmic-cornual, (b) termino-terminal, (c) isthmic-ampular.

Once the obstruction is localized, the occluded area is cut off, then the tubal lumen is canalized with a very thin plastic catheter that joins the distal and proximal tubal segments; this will serve as a guide for the suture stitches for the anastomosis.

The hemostasis has to be performed very carefully to avoid damaging the blood vessels running below the tube that irrigate the organ and carry information to the uterus and the ovary about the reproductive events.

Afterwards, suture stitches of non-absorbable material are made, 5/0 width, in the four cardinal points: mesenteric, internal, external, and superior.

Finally, the tutorial catheter is removed.

This procedure can be performed through laparoscopy and if robotic surgery is employed it's insurmountable.

The results achieved with this technique after 18 months are quite diverse and depend on the etiology which originate the obstruction. Obliteration caused by salpingitis or endosalpingiosis, pregnancies don't surpass 8% or 10%, with a percentage of ectopic pregnancies above 30%; on the other hand, if the goal was to reverse a tubal ligature, the results are between 50% and 80%, depending exclusively on the technique used to perform the ligature, with an ectopic pregnancy percentage between 2% and 10%.

Salpingostomy

It is meant to restore the permeability of the fimbrial or distal end of the tube which is obliterated by adhesions or fibrosis. As previously mentioned, the obstruction can be partial or total.

When it is partial and pre-fimbrial, the objective is to remove the ring which chokes the ampulo-fimbrial joint through dilatation; and if it were post-fimbrial, the adherence tissue fusing the fimbrias is surgically removed employing micro scissors. This procedure is known as fimbrioplasty.

For laparoscopic surgery a pair of atraumatic tweezers are employed; one of them secures the border of the tubal ostium in such a way that one of its ends is introduced inside the lumen of the tube, and the other is introduced in the serous; the second tweezers is introduced closed inside the ampullar cavity; once inside it is withdrawn open, breaking in this way the phimotic ring. Or it is introduced on the opposite end in the same way and both tweezers are removed in opposite directions tearing the phimotic ring.

When the ostium is totally obstructed—conglutination or hydrosalpinx—the tube has to be filled with methylene blue to cause the distention of the obstructed end; in this way a whitish irradiated image is observed, which corresponds to the cicatrization caused by the occlusive process. The opening is performed using a pair of micro scissors, following the path of the white scars (Video 2 in the online version at <https://doi.org/10.1016/B978-0-12-801238-3.64753-0>).

The goal is to perform three cuts in the conglutinated peritoneum as to form three petals exposing the fimbrias.

Once the opening is performed and in order to avoid a relapse of the occlusion, three nonabsorbable suture stitches (4/0 wide) can be made in each one of the petals. Another quite useful procedure to achieve this goal is the use of a bipolar coagulator with very thin tips (2 mm), to coagulate the peritoneum of each petal; this proceeding achieves the desired peritoneal retraction and eversion.

The fimbrioplasty and the correction of the conglutination achieve approximately 60% of pregnancies with a 6% rate of ectopic pregnancies. On the other hand, in Salpingostomy by hydrosalpinx the pregnancy chances doesn't exceed 30% and a fourth of them are ectopic, both within a time lapse which oscillates between 12 and 18 months after surgery (Bruhat, 1983).

Surgical Removal of Tumor Formations

Uterine myomas, endometrial polyps and ovarian cysts can be co participant for affecting a woman's fertility.

Myomas

Independently from the classic indications for myoma surgery—volume, unexpected growth, neighboring organ compression and complications (painful and/or hemorrhagic)—in reproductive medicine it should be operated when the relationship between the fibroid and uterine cavity is altered.

Interstitial myoma shall be removed when its size is larger than 5 cm or when they compromise the uterine cavity: whether they are in contact with the endometrium or invading the space of the organ in the cavity in different proportions and shapes.

Interstitial myomas

The myomas which occupy the uterine wall can be surgically removed by laparotomy or by laparoscopy.

The surgical techniques of both ways to deal with this are similar: incision of the uterine serous and the myometrium to reach the location of the tumor, being sure you reach the cleavage area to, then, with bold maneuvers divide the fibroid and remove it (Video 3 in the online version at <https://doi.org/10.1016/B978-0-12-801238-3.64753-0>).

If the surgery were laparoscopic, the division is performed with any blunt instrument and the traction of the myoma is performed with a strong tweezer; if it were laparotomic this is performed with the surgeon's finger (Video 4 in the online version at <https://doi.org/10.1016/B978-0-12-801238-3.64753-0>).

It is advised to thoroughly coagulate the whole area where the myoma was located with bipolar energy.

The closing of the wound shall be performed in several levels, at least two. The reason for this is to avoid leaving free space in the area where the myoma was located. The ideal suture material is long term absorbent monofilament: PDS II (Polidioxanone) 4/0 in the layer next to the endometrial cavity, or to close the uterine cavity if it was opened during the surgical procedure, and 3/0 for the rest of the wall, including the uterine serous.

The PDS II suture has the property of minimizing the variability of retention in the tension strength and in the speed of absorption, besides rendering a longer support of the wound during the healing process (Video 5 in the online version at <https://doi.org/10.1016/B978-0-12-801238-3.64753-0>).

At times, when these requirements are not met or not followed, the closing of the wound is made defectively, just at a superficial level, the serosa with only a couple of millimeters of myometrium. The consequence of this is that the walls of the wound don't close correctly, leaving open spaces which are filled with blood, fostering the formation of hematomas which will later be replaced by fibrous tissue; this causes the loss of elasticity of the surrounding myometrium, putting at risk the integrity of the uterine wall when a future pregnancy occurs, and exposing the patient to an uterine rip.

If there's an instance where robotic surgery stands out it is precisely the perfection with which the suture is performed; it can be stated as perfect.

When operating by laparoscopy several techniques and instruments have been designed to remove the myoma or myomas from the abdominal cavity.

- (a) *Rear colpotomy*: Implies the extraction of the myomas through an incision performed in the back of the rear sack of the vagina. It has to be of considerable size according to the dimensions of the fibroid and has the inconvenience of facilitating the escape of the gas used to make the pneumoperitoneum with the corresponding loss of vision due to the collapse of the abdominal cavity.
- (b) *Pfannenstiel micro incision*: A small size suprapubic transversal laparotomy. The criticism to this technique is that a small laparotomy has to be performed to remove the material obtained by laparoscopy, then, why not perform a laparotomy from the very beginning?
- (c) *Morcellation*: It implies the reduction of the fibroid's volume in a mechanical way. An instrument that performs circular cuts—a morcellator—is employed, which is manually or motor controlled and forms tissue cylinders with a 15–20 mm diameter, which are extracted through the surgical trocars.

It's a dangerous instrument because it has a sharp edge and if not used carefully the damage it can cause to the pelvic or viscera vessels is very serious. Furthermore, since the cuts are not perfect small rests of the myoma usually detach and are scattered through the pelvis and the abdomen; their complete removal is usually difficult to do and this minuscule remains can cause parasite myoma formations in different parts of the abdomen (Video 6 in the online version at <https://doi.org/10.1016/B978-0-12-801238-3.64753-0>).

Myomas that compromise the uterine cavity

The submucous myomas are surgically removed with the use of hysteroscope or resectoscope.

The resectoscope is an endoscopic instrument, which has a cutting system consisting of an incandescent loop fed with mono or bipolar electric power. It performs slice cuts in the tumor-like formation until a complete removal is achieved. The uterine cavity is expanded with a glycine solution when monopole power is used or a physiological solution when bipolar power is used. It's very useful if the surgeon is assisted by ultrasound scan to evaluate the limits of the cut and reduce the risk of a uterine perforation (Video 7 in the online version at <https://doi.org/10.1016/B978-0-12-801238-3.64753-0>).

Endometrial polyps

Its removal is similar to the one described for submucous myomas. The small polyps can be removed with the operating hysteroscope with the use of scissors and cauterization.

Ovarian cysts

The technique won't be analyzed for each specific case according to its etiology; it will be analyzed considering what's common among all of them.

It's worth pointing out that cystectomy is a field of laparoscopy, with or without robotics. The vision to permit this systematic isn't achieved through laparotomy because the eye of the surgeon is too far away from the pathology; while in laparoscopy, thanks to the optics, the observation is quite close and magnified; this allows to perform focused maneuvers that don't affect the integrity of the ovary.

Cystectomy demands some requirements to avoid irreversibly damaging the gonad.

- (A) *Decapsulate within the layer.* It's fundamental to locate the space separating the cyst from the ovarian parenchyma; once found, both surfaces are separated through traction and counter traction maneuvers performed with pressing endoscopic tweezers. The traction has to be performed quite close to the area where the parts separate. Traction performed too far away produces tearing of the ovary or of the cyst wall to be removed.
- (B) *Dragging of ovarian tissue.* The consequences of not observing the previous procedure will be the dragging of the gonadal tissue with the resulting damage to the organ and increased bleeding.
- (C) *Increased hemorrhage.* During the wall cyst removal, small blood vessels are damaged producing a focalized loss of blood; they should be locally coagulated with bi-polar tweezers with thin tips as soon as the hemorrhage appears; but the increase of bleeding due to an incorrect dragging of the ovarian tissue is notably more abundant; there's not a specific bleeding vessel, the bleeding is in the surface, the whole area bleeds. This phenomenon causes an excessive and abusive use of electric coagulation.
- (D) *Excessive coagulation.* Stubbornness and obstinacy to coagulate the whole bleeding surface to the point of causing a real calcination of the gonad. This excess leads, without fail, to:
- (E) *Irreversible damage of the ovarian function* (Video 8).
Irreversible damage of the ovarian function (Video 8 in the online version at <https://doi.org/10.1016/B978-0-12-801238-3.64753-0>).

Surgery of Genital Malformations

The uterine malformation which has an indisputable surgical treatment is the uterine septum and its correction is endoscopic with the use of the operating hysteroscope or resectoscope.

If the former is used, just as it was described in the polyps' paragraph, scissors or mono or bipolar micro electrodes are introduced through its operating channel, to section the fibrous septum which divides the cavity.

The use of the resectoscope is somewhat more troublesome due to its larger diameter and the need to perform a cervical dilatation. As previously mentioned, the cutting loop with a curved profile or ending in an L shape, powered with mono or bipolar energy, are ideal to use for the section of the uterine septum (Video 9 in the online version at <https://doi.org/10.1016/B978-0-12-801238-3.64753-0>).

Ultrasound scan assistance is very useful, permitting to control the limit of the section.

With Endocrinological Purposes

It could be said that the use of surgery with endocrinological therapeutic purposes has been left absolutely set aside; historically, it was left just for the treatment of the ovarian polycystosis.

Three are the described techniques to be employed: (1) Cuneiform resection of the cortical of both ovaries, whether by laparotomy or laparoscopy. It consists in surgically removing a longitudinal wedge from both ovaries, running in depth from the ovarian cortex to the marrow of the gonad. Generally, the consequences are perianxial adhesions. (2) Multiple removals of the ovarian cortex with the use of biopsy tweezers through laparoscopy, and (3) Ovarian drilling, consisting of 4–10 perforations of the ovarian cortex through laparoscopy, with a monopole or bipolar needle with laser power, with a depth of no more than 5 mm and an electric equipment with a cutting power between 30 and 40 watts, in the case of monopole power.

In the present days it can be said that they have fallen out of fashion; exceptionally, the ovarian drilling is used by some surgeons in some exceptional instances.

Conclusion

To be able to round up a conclusion in a subject as ample as reproduction surgery is almost impossible: its indications are multiple, the surgical techniques are individual for each pathology and the instruments are many; nevertheless, it could be rounded up in four basic concepts; in order for surgery to be useful in sterile treatment it has to have: (a) an appropriate selection of the patient, (b) surgeons with excellent surgical training, (c) complete and state of the art surgery instruments, (d) a proven surgical technique. Supplementary data to this article can be found online at <https://doi.org/10.1016/B978-0-12-801238-3.64753-0>.

Surgical Treatment of Asherman's Syndrome

Keith Isaacson, Harvard Medical School, Boston, MA, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Intrauterine adhesions were first described in the late 19th century but the term Asherman's syndrome was not coined until 1948 by the Israeli gynecologist Joseph Asherman. He described 29 women who had amenorrhea and had scarring in the lower uterine segment as a result of endometrial trauma. Today we use the term Asherman's syndrome to describe the presence of intrauterine adhesions. The etiology of the formation of intrauterine adhesions is not well understood. Following trauma to the endometrium by surgery, curettage or infection, a reduction in vascular growth factors or involvement of adhesion promoting cytokines may be involved (Conforti et al., 2013). Clearly, the immediate postpregnant state of the uterus places a patient at the highest risk of forming intrauterine adhesions and like most other unknowns, genetics may play a role in the uterus ability to heal with and without scar tissue.

In studies that examine the incidence or prevalence of Asherman's syndrome, we are typically missing the denominator. We know that out of 1000 women with documented Asherman's syndrome, that over half will have had a miscarriage curettage, one quarter with a postpartum curettage with the remainder having a history of cesarean section, infection such as TB, laparoscopic and hysteroscopic myomectomy, uterine artery embolization, and rarely an IUD insertion. The likelihood of developing Ashermans after a first trimester D&C has been reported to be 15%–20% (Gilman et al., 2016; Hooker et al., 2014, 2016). In patients suffering from severe Ashermans, 70% had postpartum instrumentation (Hooker et al., 2016).

As a general rule, the goal of any of the above procedures is to minimize mechanical or thermal trauma to the normal endometrium and not to disrupt the endometrial basalis layer between the functional endometrium and the myometrium. In theory, the deeper the trauma in the uterus the more likely it is to develop intrauterine scar. Moreover, it is appropriate surgical technique not to operate on pathology located on opposing walls of the uterine cavity. Since the cavity is a potential space, this would allow for two traumatic surfaces to adhere to one another. At the end of the day, however, there are no data proving that any curettage technique places a patient at greater or lesser risk for forming post procedural adhesions.

Signs and Symptoms of Asherman's Syndrome

Patients with intrauterine adhesions may be asymptomatic or suffer from severe cyclic pain and amenorrhea. The symptoms are mostly related to the amount and location of the intrauterine scar tissue. While there are several published adhesions scoring classifications, these are not related to the signs and symptoms of the condition. As a general rule, assuming there is no obstruction of menstrual effluent from the scar tissue and the patient is ovulatory, the lesser the amount of flow, the greater the amount of scar tissue. The exception occurs when there is obstruction of flow by lower uterine sear or corneal scar, the resulting hematometria will cause cyclic pain and cramping. In patients who have had an endometrial ablation, this is referred to as posttubal ablation syndrome. The complete canal obstruction at the internal os of the cervix most often occurs after a first trimester curettage.

Other than pain, hypomenorrhea or amenorrhea, intrauterine adhesions can present with recurrent miscarriage or infertility. If an embryo attempts to implant on scar tissue, there is not enough vascularity to support the placental growth. If, however, the embryo implants adjacent to scar tissue, it is likely the scar will not affect the pregnancy.

Candidates for Surgical Therapy

Before we discuss the surgical technique to correct Asherman's syndrome, it is important to identify candidates for therapy. Firstly, the patient should be symptomatic from the syndrome. That is there should be a history of cyclic pain, recurrent miscarriage, abnormal pregnancy outcome related to intrauterine scar or infertility. If a patient has scar within the uterus, light to absent menses, no pain, and does not desire future fertility, there is no need to correct the anatomy. Likewise, the patient should be aware of the likelihood of success given the type of Asherman's and the extent of the disease. It is well recognized that those patients that have more than 70% of the uterine cavity involved in scar tissue, the likelihood of a successful pregnancy is less than 30% (Chen et al., 2017). Another group of patients to consider are those who have an open cavity but hypo or amenorrhea due to the replacement of the endometrium by atrophic scar tissue. The prognosis for these patients who desire fertility, is extremely poor and they should be counseled to consider a gestational carrier or adoption.

Surgical Technique

As with most fertility sparing surgery, the goal is to restore normal anatomy while minimizing damage to surrounding normal tissue. In the case of Asherman's syndrome, the additional goal is to minimize the recurrence of the intrauterine scar tissue. The objective of the surgery is to identify the cervical canal, lower uterine segment, uterine fundus, both cornua and both fallopian tube ostia.

Pre surgical planning is extremely important prior to adhesiolysis. First a bimanual pelvic exam should be performed to determine the uterine and cervical position, anterior or posterior. Second, a transvaginal ultrasound is performed to assess the endometrial echo and thickness. In addition, a saline sonography or a 3-D ultrasound will give the surgeon a good idea of how much of the cavity is involved in scar. When the lower uterine segment is completely obliterated with associated amenorrhea, it is helpful to perform the adhesiolysis with transabdominal ultrasound guidance and a full urinary bladder. This will reduce the risk of creating a false passage, uterine perforation, and missing the uterine cavity entirely.

In order to correct the uterine anatomy while minimizing damage to normal tissue, the smallest, most effective instruments should be used. If possible, instruments that create heat (monopolar or bipolar) should be avoided. As well, there is no need to use mechanical tissue shavers to cut scar tissue and open the cavity. When 5Fr cold semi-rigid "micro" instruments are used, there is minimal risk to damage normal tissue and if a perforation does occur, there is minimal risk to external viscera.

Lysis of intrauterine adhesions should be done hysteroscopically. There is little value in performing this procedure with laparoscopic guidance (Deans and Abbott, 2010).

The laparoscope can demonstrate that a perforation has occurred and not that one is about to occur. As stated, a perforation with a 5 Fr instrument is unlikely to have clinical significance so the risk of laparoscopy is not worth the very small benefit.

Since the instruments of choice are 5 Fr semi rigid blunt tipped or sharp tipped scissors, the outer diameter of the continuous flow dual channel hysteroscope can be between 4.5 and 5.5 mm depending on the manufacturer. The best image is through a rod-lens telescope with a 12 degree foreoblique angle. Some surgeons prefer a 25 or 30 degree lens but keep in mind the instrument exits the hysteroscope at 0 degrees. Therefore the 12 degree lens allows visualization of the distal tip at a greater distance.

Transabdominal ultrasound guidance can be helpful whenever the hysteroscopic encounters complete obliteration of the cervical/endometrial canal at any level. Though the ultrasound only shows two dimensions, it does reduce the incidence of creating a false passage into the myometrium (Myers and Hurst, 2012).

There is a small amount of controversy as to whether RF energy should be used to lyse intrauterine adhesions. At the end of the day there are not enough data to support one technique over another but there are two advantages to using cold instruments to consider. First is the relatively high rate of perforation with Asherman's patients (3%–4%) (Hanstede et al., 2015). Should perforation occur with energy, a laparoscopy is needed to ensure there is no damage to the internal viscera. This is not necessary when a perforation occurs with a 5 Fr cold semi-rigid scissor. Second, it has been reported that pregnancy rates for Asherman's patients are higher when nonenergy devices are used to lyse adhesions (March, 2011).

Whether the procedure is done in the office setting with no anesthesia or the operating theater under local, regional, IV or general anesthesia is irrelevant to the outcome. The one exception is the patient feedback when there are severe adhesions. When the surgeon cuts the adhesions, there is no pain. When the surgeon cuts the myometrium, there is pain and the patient feedback can alert the surgeon that he or she is creating a false passage.

My preference is to perform hysteroscopic adhesiolysis in the office setting using the vaginoscopic technique, no speculum, no tenaculum, and no local anesthesia. It is our experience that approximately 75% of patients tolerate this well. Twenty five percent request that the procedure be performed with local or IV anesthesia. It is recommended that the patient take 400–600 mg of Ibuprofen 1 h prior to the procedure.

In addition to the hysteroscope, and the 5 Fr instruments, the room in which the adhesiolysis is being performed should have a camera, monitor, light source, and a digital capture device. A second monitor for patient viewing is helpful and provides a distraction. Fluid needs to be instilled through the hysteroscope to distend the vagina, cervix, and uterine cavity. The fluid of choice is slightly heated normal saline. The distention flow and pressure can be controlled by an inexpensive fluid pump designed for office use or by gravity or pressure bags. The distention pressure should be the minimum amount that provides adequate flow and distention. Cysto tubing helps to maintain a good flow rate and the fluid should be captured and measured as it leaves the patient or hysteroscope to ensure that fluid overload will not occur. As a rule, a young healthy patient should be able to absorb up to 2 L of saline without clinical consequence. This amount of fluid intravasation rarely occurs during the adhesiolysis procedure but large venous sinuses can be encountered.

The goal of the adhesiolysis is the restoration of the normal cavity. The adhesions can be lysed or removed. When a thick band is encountered, I will try to resect the adhesion at the base and attached wall with the microscissors and not just lyse it. There are no data that resection of an adhesion gives better outcomes than lysis. Restoration of the normal cavity can only be assured if both fallopian tube ostia are visualized. Since the opening of the tube is only 1.2 mm in diameter, this is often difficult when there are corneal adhesions and obstruction.

There are two types of Asherman's fibrosis. The first and most common are the adhesive bands that can be lysed as described above. The second type of Asherman's scar is that which replaces the normal endometrium to the depth of the myometrium including the basalis. There is no successful surgical correction of the latter type of Asherman's and it carries a very poor prognosis when over ¾ of the endometrium has been scarred. These patients should be counseled on gestational carrier opportunities or adoption.

Recurrence of Adhesions

For surgeons that treat a high volume of patients with Asherman's syndrome, it is generally accepted that the initial treatment of the intrauterine adhesions is not technically challenging. What is difficult is preventing and treating the recurrence of the scar tissue that

occurs within the first 6–8 weeks after surgery. Several adjuvants have been and are currently used in effort to minimize recurrence of the intrauterine scar tissue.

- Estradiol
- Intrauterine devices (IUD)
- Intrauterine balloon
- Second look hysteroscopy
- Antiadhesive gels and barriers
- Stem-cell therapy

While there is no standard dose of estrogen for patients who have undergone hysteroscopic adhesiolysis, a recent review suggest that there is benefit to patients desiring future fertility (March, 2011). Our practice is to prescribe 4 mg of oral estradiol daily for 30 days with a dose of 10 mg of medroxyprogesterone acetate on days 25–30 to induce a withdrawal bleed.

Physical barriers such as nonhormonal and not copper containing IUDs, Foley balloons and intrauterine balloons thought to be effective in reducing postoperative adhesion recurrence though there has never been a randomized clinical trial to demonstrate their value. Most reports describe using these in barriers for 7–10 days postsurgery (Di Spiezio Sardo et al., 2016).

Since over 90% of our adhesiolysis procedures are done in the office using a vaginoscopic technique without anesthesia, we prefer the second-look hysteroscopy method to prevent recurrent adhesions. The second procedure is done 2 weeks after the first and the third procedure is done after the withdrawal bleed at 6 weeks. The advantage is not leaving a foreign body within the cavity and being able to lyse recurrent thin adhesions. Since patients have to have their barrier removed in the office, the second look approach only requires one extra visit and no visits in the operating room. The outcomes reported are at least as effective as the barrier approach though no head to head studies have been performed (Robinson et al., 2008).

Outcomes

Spontaneous conception rates after treatment with adhesiolysis are inversely correlated with the extent of adhesive disease (Evans-Hoeker and Young, 2014). For patients with severe IUA, only 25% were able to spontaneously achieve pregnancy, compared to 53% of those with moderate disease (Xiao et al., 2014). One large retrospective study focusing on patients with moderate to severe IUA treated with adhesiolysis, IUD placement, balloon catheter insertion, antiadhesion gel, and oral estrogen therapy together were reported to have pregnancy rates of 66% and live birth rates of 64% (Xiao et al., 2014). A large retrospective study confirms overall conception rates are reported as high as 48% and birth rates less than 80%, with mean time to conception as 8.9 ± 3 months following hysteroscopic adhesiolysis (Chen et al., 2017).

Patients with Asherman's are at increased risk for pregnancy complications. There is a reported 19% combined rate of spontaneous abortion, missed abortion or stillbirth, as well as preterm delivery amongst patients with moderate to severe disease (Xiao et al., 2014). In another study, Asherman's patients after hysteroscopic adhesiolysis were reported to have a 9% incidence of miscarriage (Chen et al., 2017). This is somewhat lower than the baseline incidence of miscarriage of 20%, and is likely underrepresentative of the true incidence. Other outcomes are equally variably reported in the literature, ranging between reporting a 14% risk of abnormal placentation (e.g., accreta) (Fernandez et al., 2006) and 8% risk of postpartum hemorrhage (Chen et al., 2017), to a 63% combined rate of abnormal placentation including increta, placenta previa, and postpartum hemorrhage all together (Xiao et al., 2014). It is difficult to ascertain from the data what the actual risks are, however it is clear that moderate to severe IUA disease has a negative impact on obstetrical outcomes.

Over the past 20 years, many patients have undergone endometrial ablation to treat their heavy menstrual bleeding and subsequently had a desire to conceive. Whether the endometrial cavity is treated with heat or cold to destroy the functional endometrium, there is ultimately severe Asherman's in the treated areas. When these patients are treated, a small percentage with achieve pregnancy. The pregnancy is very high risk with perinatal mortality of 13%, prematurity over 40%, and 25% with abnormal placentation (Hare and Olah, 2005).

In conclusion, intrauterine adhesive disease once thought to be a rare phenomenon, is now known to be relatively common in patients undergoing uterine surgery and endometrial curettage in the postpregnant state. Advances have been made in the minimally invasive approach to treating Asherman's Syndrome whereas most patients can be successfully treated in an outpatient office setting without the need for regional or general anesthesia. Our frustration continues in our poor success with preventing recurrent adhesions. There is great hope for novel stem cell and regenerative therapy to recreate a functional endometrium with a normal intracavitary volume.
